Journal of the National
Cancer Institute

January 1982
Volume 68
Number 1

THE JOURNAL of the National Cancer Institute solicits manuscripts on original observations in laboratory and clinical research from all scientists. A manuscript is considered for publication with the understanding that it has not been published previously and is submitted exclusively to the Journal. Opinions expressed by the authors are not necessarily those of the publisher or its editors.

THE JOURNAL is published monthly (two volumes a year). The Secretary of Health and Human Services has determined that the publication of this periodical is necessary in the transaction of the public business required by law of this Department.

A MONOGRAPH SERIES covering proceedings of scientific meetings pertaining to cancer is also published. These books may be purchased from the Superintendent of Documents. Series subscriptions are not available and monographs are not included in a subscription to the Journal.

THE JOURNAL is for sale by the Superintendent of Documents, U.S. Government Printing Office, Washington, D.C. 20402. Price per copy, $6.00. Subscription price for two volumes per year in the United States, $65.00; foreign, $81.25. Payment is required in advance, and check or money order should be made payable to the Superintendent of Documents.

All inquiries regarding purchase of subscriptions or depository library distribution, including inquiries about missing issues and change of address, should be addressed to the Government Printing Office. The Government Printing Office requires payment in advance on all orders. Inquiries regarding missing issues or change of address for official subscriptions should be addressed to the Editorial Office, Room 850, Westwood Building, 5333 Westbard Avenue, Bethesda, Md. 20016.

Instructions to Authors

Text: Send one original and two copies. **Text-figures** (graphs, charts, and line drawings): Send one original and two copies. **Figures** (photomicrographs and photographs): Send three original glossy prints, unmounted. **Tables:** Send tabular material in typewritten form; do not submit tables as glossy prints to be photographed. The entire manuscript including footnotes, legends, and references must be typed double spaced. Single-spaced portions of a manuscript will be returned to the author for retyping. The mailing address is: Journal of the National Cancer Institute, Westwood Building, Room 850, 5333 Westbard Avenue, Bethesda, Maryland 20016.

Manuscripts should be accompanied by a covering letter from the author responsible for correspondence about the manuscript. The covering letter should contain a statement that the manuscript has been seen and approved by all authors and that all persons listed as authors have made significant (not merely administrative, technical, or supervisory) contributions to the content of the paper. The letter should also state that the manuscript or substantial portions thereof have not been previously published nor are they under consideration for publication in another journal.

Data too extensive for inclusion in a manuscript, but which may be of interest to other investigators, may be deposited with the National Auxiliary Publications Service (NAPS), c/o Microfiche Publications, P.O. Box 3513, Grand Central Station, New York, New York 10017. Authors using the NAPS facilities should indicate in a footnote how their additional data may be obtained.

Approximately one-half of all manuscripts submitted to the Journal are accepted for publication. Publication of manuscripts is contingent on transfer of copyright to the Journal. Forms for this purpose will be sent to authors when a manuscript has been approved for publication. All material published in the Journal is in the public domain; therefore, permission to reproduce any portions is not necessary. As a matter of courtesy, communication should be made to the author(s) concerned.

TITLE: Be brief (no more than 14 words, if possible), but for indexing purposes include all key words. The annual subject index is prepared directly from the titles. Titles that form complete sentences are not acceptable. Do not use abbreviations or chemical formulas in titles.

BYLINE: Supply the complete first name, middle initial, and last name of each author. Avoid use of nicknames. Academic degree is optional; however, if a degree is provided for one author, it should be provided for all authors on a manuscript. Include the name of the institution, address, and zip code for each author. Indicate address for reprint requests in a footnote on the byline.

ACKNOWLEDGMENTS: Financial aid in support of research should be recognized in a footnote. Aid in technical fields, animal care, photography, stenography, and other areas may be mentioned in a separate footnote. Indicate the title (Dr., Mr., Mrs., Miss, Ms.) and affiliation of each person acknowledged.

ABSTRACT: Provide an abstract, 150 words or less, on a separate page. The abstract should describe only *results* of the work being reported. Speculation, historical background, or reference to published works will be deleted from abstracts. Any inbred strains, outbred stocks, cell lines, or other living materials used in the work should be noted in the abstract.

TEXT: Avoid the use of laboratory jargon and abbreviations not in common usage. When possible, refrain from the use of abbreviations that form words (exceptions are PAGE, ALL). Whenever possible, write mathematical equations and chemical formulas on a single line; submit complicated chemical structures as artwork. Avoid repetition of data in the text when it is presented in tables or text-figures.

Use the following style sources: Webster's *Third New International Dictionary* and Dorland's *Illustrated Medical Dictionary* (25th ed) for spelling; *Council of Biology Editors Style Manual* (4th ed) for scientific abbreviations and symbols; *Government Printing Office Style Manual* for other abbreviations and symbols, punctuation, and hyphenation; *Collected Tentative Rules & Recommendations of the Commission on Biochemical Nomenclature IUPAC-IUB* (2d ed) for abbreviations of chemical substances; *Enzyme Nomenclature*, recommendations (1972) of the IUPAC-IUB for recommended names of enzymes and information on nomenclature of isoenzymes; *The Merck Index* (9th ed) for chemical compounds; "Standardized Nomenclature for Inbred Strains of Mice: Seventh Listing" by Joan Staats (Cancer Res 1980;40:2083-2128) for inbred mouse strains; "Standardized Nomenclature for Inbred Strains of Rats: Fourth Listing" by Joan Staats and Michael Festing (Transplantation 1973;16:221-245) for designations of inbred rat strains; *Animals for Research* (9th ed) prepared by the Institute of Laboratory Animal Resources, National Academy of Sciences, for designations of laboratory animal stocks and strains.

TABLES: Submit tabular material typed double spaced on a separate page. Computer print-outs of tables are acceptable only if they are double spaced and with satisfactory title, column headings, legends, and other textual material. Provide headings for all columns of a table and indicate units of measurement where applicable.

TEXT-FIGURES: Refer to graphs, charts, and line drawings as text-figures. Make the abbreviations on text-figures identical to the abbreviations used in the text and legends. Symbols and lettering should be large enough to be legible if reduced. Glossy prints or original drawings in black ink are acceptable; orient vertically instead of horizontally.

FIGURES: Refer to photomicrographs and photographs as figures. Figures and their legends should fit a 7.5- by 9-inch dimension. Calculate that nine typewritten lines of legend will require 1 inch of vertical space. Type figure legends on a separate sheet and identify in the legend any lettering used on the figure. Trim photographs to show only important areas. Do not number face of photographs; use the back or overlay to indicate the top and number of each. Printed indicators may be included on photographs; do not use hand-drawn indicators. *Insert internal scale markers on all photomicrographs.* Color photographs must be grouped as a single plate. For color reproduction, submit both color transparencies and high-quality black and white reproductions. The need for color must be documented before it will be considered.

REFERENCES: Use any recent issue of the Journal as a style guide for reference lists. Number references in order of citation in both text and reference list. For periodicals, provide author(s), title of paper, journal, year, volume, and first and last page numbers. For books, give the author(s), title, name(s) of editor(s), location and name of publisher, year, pertinent chapter or section title, and page numbers. Follow *Index Medicus* for punctuation and abbreviations. Citations of papers in preparation or submitted for publication, unpublished observations, and personal communications should be noted parenthetically in the text. Do *not* include them in the reference list. The accuracy of all references is the responsibility of the authors and not of the editorial staff.

LETTERS TO THE EDITOR should pertain to recent articles in the Journal and should not contain new data unless relevant to the discussion of a particular paper. The authors addressed will be invited to reply to comments before correspondence is published. Letters will be edited by the Staff, subject to contributor approval.

FURTHER DETAILS on the preparation of manuscripts are set forth in the document "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" prepared by the International Steering Committee of medical editors (*see* Am Rev Respir Dis 1979;119:3-10/ Ann Intern Med 1979;90:95-99/ Br Med J 1979;1:532-535/ or Lancet 1979;1:428-430).

Howard B. Andervont, *D.Sc.*—A Tribute

Dr. Howard Bancroft Andervont, who died on March 11, 1981,[1] at the age of 83, served as Scientific Editor of the *Journal of the National Cancer Institute* from 1961 until his retirement from the Public Health Service in 1968. Dr. Andervont's association with the National Cancer Institute (NCI) had its beginnings in 1930 when he became the first professional staff member of the Office of Cancer Investigations in Cambridge, Massachusetts.[2] This group later became part of NCI and moved from Cambridge to Bethesda, Maryland, in 1939. His research work at NCI included significant contributions to the study of induced and spontaneous tumors in mice and the role of environment in the occurrence of breast cancer in mice. He pioneered the use of inbred animals for such studies.[3] When the NCI underwent a major reorganization in 1947, Dr. Andervont was named to head the Biology Section. This position later became Chief of the Laboratory of Biology, a post he held until 1961 when he became Editor of the *Journal of the National Cancer Institute*. He was active in many scientific societies and he served on numerous committees. In 1955 he was president of the American Association for Cancer Research.

In recognition of his important contributions to cancer biology and his editorial accomplishments, the Board of Editors of JNCI pays tribute to Howard B. Andervont, *D.Sc.*

Neoplasms Following Childhood Radium Irradiation of the Nasopharynx [1,2,3]

Dale P. Sandler, [4] **George W. Comstock,** [5,6] *and* **Genevieve M. Matanoski** [5,7]

ABSTRACT—Eighteen to 35 years after admission to a clinic for the prevention of deafness, no increased overall cancer risk could be detected among 904 persons who had been treated with nasopharyngeal radium irradiation when compared with the risk among 2,021 persons who were either treated surgically or not treated at all, although there were differences at specific sites. An increased risk of developing both benign and malignant head and neck tumors was found among irradiated persons. Whereas no one head and neck site showed a statistically significant excess, a slight excess of brain cancer occurred 15-20 years after radium treatment. No increase in thyroid cancer risk was observed, a result possibly attributable to the low radiation doses to this organ and the relatively small population irradiated.—JNCI 1982; 68:3-8.

Previous studies of populations treated with head and neck irradiation have demonstrated a link between head and neck irradiation and cancer, particularly for thyroid cancer at doses to the thyroid gland in the range of 100-1,000, rad (*1-6*). In addition to thyroid cancer, increased rates of leukemia (*2, 7, 8*), benign and malignant salivary gland tumors (*2, 4, 7*), benign and malignant brain tumors (*7-9*), other malignant neoplasms (*6-8, 10*), and benign thyroid tumors (*2, 8, 10, 11*) have been reported following head and neck X-ray irradiation.

The evidence that radiation doses lower than 20 rad are carcinogenic is less conclusive than for larger doses. Whereas Modan et al. (*7*) and Ron and Modan (*11*) demonstrated a fourfold to fivefold thyroid cancer risk following doses of 9 rad to the thyroid from treatment of tinea capitis, Shore et al. (*8*) found no increased thyroid cancer risk after similar treatment. Other suggestive evidence of increased thyroid cancer risk at doses as low as 20 rad includes the occurrence of one or two cancers in irradiated populations when none were expected (*9, 10*).

Screening programs for detection of thyroid cancer among irradiated persons (*12-14*) confirm a thyroid cancer risk and demonstrate a risk for benign thyroid tumors. In these analyses, the lack of appropriate comparison groups studied with equal care for occult thyroid tumors may have led to an overestimation of the thyroid cancer risk (*15, 16*). This situation may also be true for questionnaire surveys of irradiated populations, especially those studies in which the population has been resurveyed three or four times. The increasing ratio of benign to malignant tumors reported for these radiation-exposed populations on successive examination is consistent with more extensive case finding for subsequent surveys (*2, 8*).

The present study affords an opportunity to examine the possible effects of low-dose irradiation in a population that had no prior screening for such effects. Study subjects were treated during childhood with radium irradiation of the nasopharynx. The treatment, which reduced the size of the adenoids, was delivered to reduce the frequency of ear, nose, and throat infections and prevent the mild hearing loss associated with adenoid hypertrophy (*17*). The radium treatment involved inserting radium-containing applicators into the nasopharynx, where the resulting radiation dose was greatest. Other nearby sites, such as the brain and pituitary gland, also received some exposure. Unlike many of the other types of head and neck irradiation that have been studied, most radiation doses to the thyroid gland were lower than 20 rad.

METHODS

Study population and follow-up.—The study population consists of 2,925 persons from Washington County, Maryland, who were seen between 1943 and 1960 at a clinic established to prevent deafness among children. The population includes all persons who were first seen prior to 1960 and had become 21 years of age or had stopped coming to the clinic by 1978. Of the eligible study cohort of 2,925 persons, 904 (31%) had been treated with nasopharyngeal radium irradiation. The remaining 2,021 were treated with tonsil and

adenoid surgery or were given other treatment to relieve their symptoms.

The entire cohort was traced through a special county census that had been conducted in 1963 and again in 1975 (*18*), through telephone books and city directories, through departments of motor vehicles in Maryland and neighboring states, and through obituaries and death certificates. Other information used in tracing procedures included names of parents, names of siblings also seen at the Washington County Health Department clinics, address at time of visits to the clinic, and school attended.

Each traced individual was mailed an explanatory letter and a questionnaire for self completion. At the request of the Washington County Health Department, persons who had been irradiated were so notified. The questionnaires, however, were identical for the groups exposed and not exposed to radiation. Four main areas were emphasized: radiation exposure, tumor history, conditions potentially relating to pituitary gland function, and difficulty with hearing.

The first questionnaire mailing was followed by a second mailing to initial nonrespondents. Persons who did not return a questionnaire were contacted by an interviewer who obtained the questionnaire data over the telephone. Interviewers were not informed of the exposure status of study subjects. Nonrespondents living in Washington County were visited at home when telephone interviews were not possible.

To determine cause of death, death certificates were obtained for persons known to have died. Questionnaire reports of tumors, "lumps," or "growths" were followed up with requests to hospitals and physicians for pathology reports and diagnostic summaries, which were obtained for 80% of all hospitalizations for which the reported cause seemed in any way to be related to malignant or benign tumors. Financial restrictions precluded any review of pathology specimens.

To minimize reporting bias that might result from notification to the group about their past irradiation and from suggestions that they be examined, only illnesses diagnosed prior to the date of the first study letter were included in the analysis. For a subsample of the population who remained in Washington County, reported hospitalizations were compared with those gleaned from Washington County Hospital diagnostic indices and from the Washington County hospital-based tumor registry. There was no indication of over-reporting or under-reporting of hospitalizations for either group.

Radiation exposure and dosimetry.—When irradiation to the adenoids was recommended, a radium applicator, containing 50 mg of radium salt in a 15-mm length chamber screened with 0.3-mm monel metal, a nickel alloy, was inserted into each nostril. When in place, the radium chamber extended from the eustachian tube orifice back to the posterior nasopharyngeal wall, as close to the adenoids as possible. The monel metal filter allowed both β- and γ-rays to reach the surrounding tissues. The applicators were left in place an average of 12 minutes. Treatments were generally given three times at 2-week intervals. Occasionally, a treatment series was repeated after approximately 6 months (*19*).

The radiation doses at various distances from the applicators are listed in table 1. These doses were estimated with the use of a method that takes into account the varying energies and absorption fractions of the different products of radium decay and known properties of the radium applicators (*20*). The radiation dose is high at 1 cm, the area immediately surrounding the applicators, and drops off quickly as the distance from the applicators increases.

The distances from different tissues to the applicators are a function of the age and size of each individual at the time of treatment and the exact positioning of the applicators. These measurements were not available for the study population, but estimates of different tissue doses have been made by calculations for "average individuals" in each age group. Measurements were taken from skull films of individuals who were between 2 and 16 years old but were not in the study population. Distances from the radium applicators in the nasopharynx to the thyroid, pituitary, and salivary glands are shown in table 2. These measurements were in agreement with adenoid-thyroid distances reported by Hazen (*4*) for individuals between ages 4 and 17 years. Whereas the nasopharynx and eustachian tube orifices received approximately 700 rad, the pituitary gland and lower portion of the brain received approximately 78 rad from the standard three treatment series. In most instances, the thyroid gland was 6 to 12 cm from the applicators in the nasopharynx and received exposures ranging from less than 5 to 20 rad. The distribution of study subjects by age at first treatment and total number of treatments given are shown in table 3.

Data analysis.—Cancer incidence rates were based on person-years of observation. For persons with cancer, time at risk extended from the date of first treatment to the date of diagnosis of first cancer occurrence (or date of death if the information was obtained only from a death certificate). For persons without cancer, time at risk extended to the last date of observation.

The incidence rates for benign tumors and skin cancers were calculated only on the basis of the

experience of individuals who completed a questionnaire. Incidence rates of cancers of sites other than skin were calculated on the basis of experience of all located individuals.

Standardized incidence ratios were used to adjust the crude cancer incidence rates for differences in ages and years of follow-up between subgroups exposed and not exposed to radiation. An indirect adjustment procedure that used an internal standard was used. We computed the standardized incidence ratios by using a multiplicative log-linear model described by Breslow and Day (*21*) and by using a computer program developed by Tonascia (*22*). With this program, maximum likelihood estimates of the ratio of the number of observed events in the groups exposed and not exposed to radiation to that expected on the basis of pooled standard rates adjusted by age/year for the entire study population were calculated. The ratio of the calculated standardized incidence ratios for the irradiated and nonirradiated subgroups provides a maximum likelihood estimate of the RR of that outcome. Confidence intervals were placed on the observed RR (ratios of two Poisson parameters) with the use of a method described by Ederer and Mantel (*23*) and modified by Hamman (*24*) in cases where age/year adjustment altered the observed RR.

RESULTS

Ninety percent of the study population was either located (87%) or determined to be dead (3%) (table 4). Tracing efforts were equally successful for persons exposed and not exposed to radiation. Located individuals were similar to those not located with respect to age at first clinic visit, year of birth, sex, race, reason for clinic visit, and examination findings.

Of 2,135 study subjects who were located alive, 84% completed a questionnaire either by mail, telephone, or home interview. Questionnaires were completed by mail for 60% of the respondents and by interview for 40%. A slightly greater proportion of the irradiated group completed a questionnaire (86%) than did the nonirradiated group (83%) (table 4).

Study subjects exposed and not exposed to radiation were not substantially different in mean age at start of follow-up, average length of follow-up, race, or sex (table 5). Irradiated and nonirradiated study subjects were also compared with regard to a number of clinical parameters at the first clinic visit. The 2 groups did not differ by family history of deafness, hearing loss at clinic visit, or frequency of colds. Radiation-exposed individuals, however, were more likely than others to have had a prior tonsillectomy and to have had frequent ear infections.

Tumor Incidence

The tumor incidence for exposed and nonexposed subjects is compared in table 6. The RR, adjusted for differences in age at entry into the study and in number of years of follow-up, are also shown.

There were no differences in the overall incidence of malignant neoplasms (RR = 1.1) or benign neoplasms (RR = 1.0), but there was a statistically significant overall excess of malignant neoplasms of the head and neck among exposed subjects. This excess was accounted for mainly by three brain tumor deaths for subjects exposed to radiation. The other malignant tumor was an undifferentiated anaplastic cancer of the soft palate. The RR of 1.6 for benign neoplasms of the head and neck was not statistically significant, but when combined with malignant neoplasms, the twofold increase in all head and neck neoplasms was statistically significant.

Thyroid cancer was not reported by either irradiated or nonirradiated individuals. There was, however, a

twofold increase in the risk (not statistically significant) of benign thyroid neoplasms. There was an increased risk of neoplasms of the lymphatic and hematopoietic tissue (RR=1.7) and a decreased risk of breast cancer (RR=0), but neither risk was statistically significant.

Analyses were repeated separately for each sex. No additional differences of any consequences were observed.

Relationship of Radium Dose to Tumor Incidence

The average number of radium treatments given the exposed group and the average treatment age are shown in table 7. The number of treatments given persons who developed head and neck tumors did not differ from that of the irradiated group as a whole. Radiation-exposed individuals who developed head and neck tumors did not receive greater irradiation (mg-hr) than did other radiation-exposed subjects. In fact, because they were older at first radiation exposure, the radiation dose to the lower portion of the brain for the 3 persons who died from brain tumors approximated 44-78 rad, which was lower than the dose for the remaining radiation-exposed persons. Those who developed benign thyroid tumors had radiation doses to the thyroid gland between 6.5 and 9.3 rad.

DISCUSSION

An increased risk of developing tumors of the head and neck has previously been demonstrated for persons who were given X-ray treatment for benign head and neck disorders. Thyroid tumors have most often been reported, possibly due to the types of irradiation treatments that have been studied. The treatments for enlarged thymus glands, enlarged tonsils and adenoids, and hemangiomas of the head and neck usually in-

cluded the thyroid gland in the radiation ports. The resulting radiation doses to the thyroid gland were generally in excess of 100 rad, and thyroid tumorigenesis has been most convincingly demonstrated at or above this level.

Many of the studies of persons with head and neck irradiation that have appeared in the literature have relied on population cancer rates (*5, 7, 9*) or cancer rates among siblings (*2, 4, 7*) for statistical comparison. One potential shortcoming of studies of groups exposed to radiation for treatment of some medical condition is that the medical condition itself may be related to later cancer risk. Furthermore, for certain tumors with a familial component, cancer risk from irradiation could be underestimated when sibling controls are used. In the present study the radiation-exposed group and comparison group consisted of persons who were seen at the same clinic for similar reasons. The 2 groups were also similar for a variety of economic, medical, and ethnic factors. The possibility that individuals who did not receive radiation exposure might have a cancer risk different from those who were treated cannot be ruled out. However, this possibility is less likely to be so than with a general population comparison.

The size of the radiation-exposed population in this study is inadequate to detect with reasonable power small increases in cancer risk at specific sites. However, large populations of radiation-exposed individuals are not easily identified. Nonetheless, consistency of suggestive findings in different populations may be sufficient to establish the presence of a disease risk. In addition, whereas the existence of no effect can never be proved, it is possible, by use of data from smaller studies, to define limits of disease risk. The overall increased incidence of benign and malignant head and neck tumors among irradiated subjects in the present study is consistent with what has been found in other populations.

In this study, by far the greatest radiation dose was to the nasopharynx and eustachian tube orifices. The applicators probably placed the radium source no more than 2-4 cm from the pituitary fossa. The nasal passages, sinuses, larynx, pharynx, and salivary glands generally were within 8 cm of the applicators and were thus likely to have received radiation doses that were greater than 10 rad. The thyroid gland, which was further from the applicators, received doses that most often ranged from 20 to 5 rad or fewer.

The one cancer site that did appear to be in excess among the irradiated subjects in this study was the brain. A possible etiologic role of radiation in the development of brain tumors has been demonstrated by others (*4, 7-9*). The most convincing evidence has come from studies of persons irradiated for tinea capitis (*7, 8*), for whom brain doses were estimated to have been between 140 and 150 rad at the surface and 50 rad at the pituitary fossa. In this study, the average pituitary dose following nasopharyngeal radium irradiation was between 44 and 177 rad. Brain doses were likely lower than this, being higher centrally and caudally and lower at the cortex. Two of the tumors were astrocytomas; autopsy information was not available for the third tumor. Irradiation-related brain tumors are often meningiomas (*7, 25*), perhaps because most radiation sources deliver the highest doses to the surface of the brain. However, 2 of the 6 tumors reported by Shore et al. (*8*) were astrocytomas.

The crude cumulative brain tumor incidence rate for radiation-exposed subjects in our population was 3.7 per 1,000 individuals, which is higher than that reported at 1.4 by Modan et al. (7) or at 2.8 by Shore et al. (*8*). The 3 tumors we found were all diagnosed between 15 and 20 years after treatment, which is consistent with the latent interval reported by Modan et al. (7) and Shore et al. (*8*). The average age at treatment of individuals with brain tumors was 11 years old, and all 3 patients received only the standard number of radium treatments.

Only 1 other malignant head and neck tumor was reported for study subjects. This was a cancer of the soft palate in an individual who received 10-20 rad to the soft palate.

Although no thyroid cancer was observed in the present study, the possibility that thyroid doses as low as these might be carcinogenic cannot be ruled out, because the study sample size was too small to detect less than an eightfold cancer risk with 80% power. Furthermore, the use of a questionnaire rather than an examination to determine tumor incidence reduced the likelihood of finding tumors that might exist.

Although the incidence of thyroid cancer in this population may have been underestimated, it is also possible that other studies have overestimated the risk because of preferential case finding (*15, 16*). For the present study, prior knowledge of radiation exposure and effects is not likely to have led irradiated individuals to preferentially seek medical care. Radiation-exposed individuals did not often associate the radium treatments with radiation, because no X-rays were used. Although 60% of radiation-exposed individuals reported knowing they had received treatments (as did 4% of the group not exposed to radiation), only 12% of the irradiated group reported asking a physician about radiation exposure. Furthermore, only 7% of irradiated subjects and 4% of nonirradiated subjects reported having thyroid scans.

Although we reported the incidence of benign thyroid nodules in the irradiated group to be twice that in the nonirradiated group, this finding could easily have occurred by chance. An increased risk of developing thyroid adenomas has been reported for irradiated individuals (*8, 11*). None of the thyroid nodules we report have been classified as adenomas, but because we did not review pathology specimens, we cannot be sure that none of the nodules were true adenomas.

If the slight increase in benign thyroid tumors in the radiation-exposed group is not due to chance, it may be related to thyroid irradiation, or it might also be due to pituitary irradiation. As in the populations irradiated for tinea capitis (*7, 8*) and in other populations for whom increased thyroid tumor risks have been confirmed (*4, 26*), the individuals in our study population received substantial doses of radiation to the pituitary gland along with lesser doses to the thyroid gland. Pituitary irradiation is thought to increase production of thyroid-stimulating hormones (*4, 27*) and excessive thyroid stimulation may play a role in the development of benign thyroid tumors in addition to that played by minimal radiation doses to the thyroid gland.

The absence of breast cancer among the radiation-exposed women when five cases were reported for the nonirradiated group is interesting in view of the fact that the questionnaire was designed to detect abnormalities that might be related to pituitary function. A decreased incidence of breast cancer has also been reported for one other population that received substantial pituitary exposure from nasopharyngeal radium treatments (*4*).

ADDENDUM

After completion of the survey, one malignant thyroid tumor was reported by an individual exposed to radiation. This indicates that a thyroid cancer risk might be demonstrated with longer follow-up. However, this could also reflect increased medical surveillance following notification of irradiation.

Epithelial Dysplasia in Nipple Aspirates of Breast Fluid: Association With Family History and Other Breast Cancer Risk Factors [1,2,3]

Nicholas L. Petrakis, [4,5] **Virginia L. Ernster,** [4] **Eileen B. King,** [4] *and* **Susan T. Sacks** [4,6]

ABSTRACT—Because of the strong association of epithelial dysplasia and breast cancer, the extent to which dysplasia of breast fluid epithelial cells obtained by nipple aspiration is associated with breast cancer risk factors was investigated. A significantly higher proportion of women who had a first-degree family history of breast cancer had dysplastic cells in breast fluid than women who had no such history. When family history status was correlated with various breast cancer risk factors, higher proportions of women with dysplasia were found among those who had a first degree family history of breast cancer and for whom certain other risk factors were present, which suggested additive and synergistic effects of these factors on breast epithelium. Breast epithelia of women with a first-degree family history of breast cancer may be more prone to abnormal differentiation in response to environmentally conditioned risk factors.—JNCI 1982; 68:9–13.

Breast gland epithelial alterations and abnormalities (hyperplasia, atypical hyperplasia, dysplasia, and carcinoma in situ) have been identified in breast tissue associated with carcinoma and appear to reflect a sequence of histopathologic events antedating frank cancer (*1, 2*). Breast fluid contains epithelial cells that are desquamated from the epithelial lining of the ductal-lobular system of the breast. Beginning in 1958, investigators have reported the occurrence of abnormal epithelial cells in nipple aspirates of breast fluid (*3–7*). Studies correlating breast fluid cytology with breast histopathology have shown that atypical hyperplastic epithelial (dysplastic) cells in nipple aspirates are shed from ductal-lobular epithelium and that this cytologic abnormality is associated with the presence of cancer (*6–8*). In a recent analysis of breast fluid from 3,208 women, cytologic dysplasia was present in 13.9% of asymptomatic women, in 19.5% of women whose tissue biopsy indicated benign disease, and in 58.6% of breast cancer patients (*9, 10*). Because of the strong association of dysplasia with breast cancer, we investigated the extent to which dysplasia of breast fluid epithelial cells was associated with breast cancer risk factors.

It has been known for many years that breast cancer has a familial component. Women whose first-degree relatives (mother, sister, or daughter) had breast cancer have a twofold to threefold increased lifetime risk of developing the disease, and they are even more at risk if the familial cancer was premenopausal rather than postmenopausal (*11*). An allele that increases susceptibility to breast cancer in certain very high-risk families, apparently linked to the polymorphic glutamate-pyruvate transaminase locus on chromosome 10, has been reported (*12*). How such a "susceptibility gene" might function to predispose to breast cancer is unknown, but the finding strengthens the likelihood that genetically determined susceptibility to breast cancer may exist in the general population.

An obvious site for the detection of such a genetic influence might be the breast epithelium itself. We present a preliminary analysis of the possible effect that risk factors have on breast epithelial cytology in terms of the classic nature-nurture model, whereby "genes plus environment equals phenotype." In this model the phenotype (cytologic dysplasia) results from a combination of "genetic" susceptibility (a first-degree family history of breast cancer) and "environmentally influenced" factors (other possible breast cancer risk factors). The model, obviously, is an oversimplification because environmental factors may play a role in family history, and genetics may influence reproductive and other so-called environmental characteristics.

MATERIALS AND METHODS

The women for this study were volunteers examined at the Hospitals and Clinics of California, San Francisco; the Breast Screening Center of Northern California, Oakland, Calif.; and other community health and screening centers. All women completed a questionnaire on their demographic, clinical, marital, reproductive, and other characteristics. A specially trained nurse or a physician examined their breasts. Clinical evaluation of breast status was recorded as normal or as clinical gross fibrocystic disease. Women who had had cancer were excluded from this report. Aspiration of fluid was attempted from both breasts by a breast pump technique consisting of a modification of the Sartorius suction cup device which is placed over the nipple and is attached to a 10-ml syringe (*4, 13*). Retraction of the syringe creates a negative pressure in

the cup, yielding fluid that is collected in capillary tubes. The methods used in the preparation of the breast fluid for cytologic examination have been described previously (*6, 7*).

The breast fluid specimens were classified cytologically into 2 groups: *a*) normal or showing benign hyperplasia and *b*) showing dysplasia, with various degrees of atypia (figs. 1A–D). The dysplasia group with the significant breast epithelial abnormality is characterized by groups of epithelial cells and single cells that show overall nuclear enlargement, variation in nuclear size, chromatin pattern and nucleolar prominence.[7]

In our analysis, we included only women from whom satisfactory bilateral fluid samples were obtained for cytologic examination. An independent analysis of unilateral samples revealed results similar to those obtained with bilateral samples. The criterion for a satisfactory smear was the presence of colostrum (foam) cells indicating that a breast fluid sample had been obtained. The analysis was limited to white women under age 50, in view of our previous findings and those of others that secretory patterns vary by race and age (*13, 14*). Breast fluid can be obtained from about 70% of white women between 30 and 50 years of age. The percentage drops sharply in older women, making secretors over age 50 much less representative of their age group than younger secretors. Inasmuch as family history of breast cancer is thought to be a more significant factor in breast cancers that develop earlier in life than in those that occur later in life, the under-50 age group seemed the most plausible one for our inquiry. Our final study population comprised over 1,100 white women under age 50, of whom 15.3% were found to have cytologic dysplasia in one or both breast fluid samples.

A number of breast cancer risk factors were compared between women with dysplasia (cases) and women with normal nipple aspirates (controls), including age at menarche, parity, age at first pregnancy, nursing history, gross fibrocystic disease as diagnosed by physical examination, use of oral contraceptives and menopausal estrogens, and first-degree family history of breast cancer.

Gross fibrocystic disease status was based solely on physical examination by physicians and by trained and experienced nurses using standard criteria. While some differences in this diagnosis would be expected among examiners, it is likely that most would agree on the presence of gross fibrocystic disease. Gross fibrocystic disease is prevalent among white U.S. women, but only a small proportion of biopsy specimens are taken from women with this disease. The women in our study consist of the group with clinical evidence of fibrocystic disease who at the time of examination did not warrant surgical intervention. Other findings indicate that even greater proportions of women have microscopic evidence of fibrocystic disease (*15*).

Analytic methods were those standard to case-control studies, including estimation of the relative risk of cytologic dysplasia associated with various factors by means of the odds ratio and its 90% confidence intervals. The data were adjusted for age by the method of Mantel and Haenszel (*16*).

We investigated the following hypotheses: A) The risk factors for breast cancer are associated with epithelial dysplasia in breast nipple aspirates. B) The relation between family history of breast cancer and dysplasia holds when other variables are controlled. C) First-degree family history of breast cancer and fibrocystic disease interact to increase risk of cytologic dysplasia in breast fluid.

RESULTS

Hypothesis A.—Table 1 shows the estimated risk ratio and 90% confidence limits (age-adjusted) of cytologic dysplasia for several major factors thought to influence risk of breast cancer as well as for the minor factors (i.e., use of oral contraceptives and menopausal estrogens). Only family history of breast cancer was found to be positively associated with cytologic dysplasia; clinically palpable fibrocystic disease was of borderline significance. Early menarche, nulliparity,

TABLE 1.—*Cytologic dysplasia in nipple aspirates associated with breast cancer risk factors*[a]

Risk factors	Odds ratio	90% confidence interval
Menarch: ≤12 vs. ≥13 yr of age	0.94	0.71–1.25
Parity: nulliparous vs. parous	1.04	0.72–1.50
Age at first pregnancy: ≥26 vs. ≤25 yr of age	1.26	0.90–1.80
Nursing: never vs. ever	0.71	0.52–0.98[b]
Clinical fibrocystic disease: present vs. absent	1.21	0.89–1.63
Family history of breast cancer (first degree): positive vs. negative	1.60	1.10–2.32[b]
Oral contraceptive use: ever vs. never	1.21	0.88–1.68
Menopausal estrogen use: ever vs. never	0.72	0.51–0.96[b]

[b] Mantel-Haenszel estimates of odds ratios, adjusted over categories of age in decades. In all comparisons, the referrent category was women who were at lower risk for a particular risk factor. The 90% confidence interval does not overlap 1.00.

---

[7] Lesions intermediate between benign and malignant disease have been called by a variety of terms. "Dysplasia" is the widely accepted term for describing such lesions of the uterine cervix. In the past, mammary dysplasia has meant any one or a combination of breast lesions in a broad spectrum of benign breast disease. We use the term "dysplasia" to describe epithelial atypia (of varying degrees of severity) of nipple secretion specimens and of breast tissue from biopsy or mastectomy. Although we subclassify the dysplasia of breast duct epithelium as mild, moderate, or severe, the results of subclassification will not be discussed here. In previous reports (*6–8*), we used the term "dysplasia" to describe severe atypia and "atypical hyperplasia" for lesser degrees of breast duct epithelial abnormality. Here the categories "atypical hyperplasia" and "dysplasia" are lumped together as "dysplasia."

age at first pregnancy, or oral contraceptive use showed no significant relation to abnormal breast fluid cytology. Never having nursed and using menopausal estrogen were negatively associated with cytologic dysplasia. The positive association of cytologic dysplasia with family history of breast cancer directed our attention to the genetic susceptibility model and gave impetus to the remaining analyses.

Hypothesis B.—We calculated the relative risk of dysplasia associated with a positive first-degree family history of breast cancer across subgroups of women differing with respect to the variables in table 1. Information on family history was available for 1,133 women, of whom 141 (12.4%) had a first-degree family history of breast cancer (table 2). Across strata, with one exception, family history of breast cancer was consistently associated with an increased risk of cytologic dysplasia, although the finding did not always attain statistical significance. When such variables as age at first pregnancy or clinical fibrocystic disease were controlled, the positive association between family history of breast cancer and cytologic dysplasia was maintained.

Hypothesis C.—Because family history of breast cancer and gross fibrocystic breast disease are important risk factors for both cytologic dysplasia and breast cancer, we wanted to know whether the combination of both factors increased risk of dysplasia beyond that observed when only one factor was present. That is, do first-degree family history of breast cancer and fibrocystic disease interact to increase risk of cytologic dysplasia in breast fluid?

TABLE 2.—*Cytologic dysplasia in nipple aspirates associated with positive family history of breast cancer, controlling for selected variables*[a]

[c] 90% confidence interval does not overlap 1.00.

We set at 1.00 the risk of dysplasia when neither a positive family history of breast cancer nor clinically palpable fibrocystic disease was present. We then calculated the odds ratios of dysplasia for women with fibrocystic disease alone, for those with a family history of breast cancer alone, and for those with both factors present. Table 3 shows an elevated risk in the presence of either factor alone (1.29 and 1.63); the risk was increased (to 1.91) in women who had both a family history of breast cancer and gross clinical fibrocystic disease. From these data one might conclude that family history of breast cancer and gross fibrocystic disease act additively to increase risk of dysplasia of epithelial cells in breast fluid aspirates.

DISCUSSION

Our findings indicate that among white women under 50 years of age *a*) dysplasia of epithelial cells in breast fluid aspirates is likely to be associated with a first-degree family history of breast cancer; *b*) the relationship holds if we control for other risk factors; and *c*) the relationship is strengthened in the presence of gross fibrocystic disease.

The outcome of interest in our study was breast fluid epithelial dysplasia, not breast cancer. Histopathologic studies are inconsistent that seek to determine whether atypical epithelial proliferation in benign breast lesions is associated with breast cancer (*17-20*), but, clearly, only a small proportion of women who undergo breast biopsy eventually develop breast cancer. Conversely, it would not be expected that all women having epithelial dysplasia in nipple aspirates would develop breast cancer. Instead, it seems more likely that epithelial dysplasia represents the response of the breast epithelium to a variety of chemical and endocrine influences. Changes in breast fluid cytology may be analogous to those found in Papanicolaou smears of the cervix in which dysplastic epithelium undergoes regression, persists for prolonged periods, or, in relatively rare instances, progresses to carcinoma in situ. Our criteria for the cells of dysplasia adhere to a definition of abnormal cells with conventional histopathologic criteria that have included a broad spectrum of benign breast diseases with or without duct epithelial atypia. Thus risk factors for dysplasia of breast fluid epithelial cells and breast cancer would not necessarily be expected to be identical. Not all women yield breast fluid when aspiration is attempted, and about one-fifth of fluid samples obtained are unsatisfactory for cytologic analysis. To the extent that breast epithelia of nonsecretors or scant secretors might not be similar to those of secretors, our findings may not be applicable to the entire population of white women under age 50.

Our findings strongly indicate that women with a family history of breast cancer and fibrocystic disease have a significantly greater risk of epithelial dysplasia in breast fluid, which suggests several areas for future investigation. The elevated odds ratios found in women with a positive family history of breast cancer when controlled for other risk factors need further study. We have demonstrated that the breast epithelia are in contact through metabolic and secretory mechanisms with exogenously and endogenously derived chemicals, including mutagenic and carcinogenic substances (*21–24*). We have detected in breast fluids substances giving positive Ames tests and, recently, cholesterol epoxides in a significant number of women. Cholesterol epoxides have been reported to be potent transforming substances, to damage chromosomes, to stimulate DNA repair in vitro, and to be carcinogenic in animals (*25–28*). The secretion of toxic and possibly carcinogenic substances by the breast might cause detectable morphologic changes in breast epithelium. These and other substances might exert greater effects on genetically susceptible epithelia of women with a family history of breast cancer, especially in the presence of fibrocystic disease. Future studies will attempt to determine whether the presence of such substances is related to the occurrence of epithelial dysplasia reported here.

Successful Transplantation of a Human Leukemia Cell Line Into Nude Mice: Conditions Optimizing Graft Acceptance[1,2,3,4]

H. W. (Löms) Ziegler,[5,6,7] **Glauco Frizzera,**[6] *and* **Fritz H. Bach**[5,6,8,9,10]

ABSTRACT—Conditions were determined for successful subcutaneous tumor development of MOLT-4 human T-cell leukemia cells in BALB/c nude (*nu/nu*) female mice. MOLT-4 cells injected alone at one site resulted in tumors in none of 21 mice, whereas MOLT-4 cells injected with X-irradiated human fibrosarcoma cells (HT-1080) at another site resulted in tumors in 5 of 21 mice. When X-irradiated three times with 200 rad over a 3-week period and then inoculated with MOLT-4 cells and X-irradiated HT-1080 cells, 19 of 25 mice developed tumors, which indicated that a combination of X-irradiation of the recipients and inoculation of an admixture of the leukemia cells with X-irradiated fibrosarcoma cells markedly increases tumor incidence. The cells growing in the tumors had the characteristics of MOLT-4, as assessed by marker studies and histology.—JNCI 1982; 68:15-18.

Many human solid tumors grow readily after transplantation into nude mice; this in vivo model has been used to assess the susceptibility of malignant cells to chemotherapy, radiotherapy, or immunotherapy (*1*). Growth of human leukemia cells following transplantation into nude mice is less successful; after sc injection into nude mice, only a few cell lines and a few fresh leukemia cells from patients have been reported to grow (*2, 3*). At least two reasons may account for this low success rate. 1) In contrast to solid tumors, leukemias usually grow by infiltrating the local tissue; no nodules thus form at the injection site, which may be due to the lack of the AGF (*4*). 2) Nude mice have high NK activity, and leukemia cells can be susceptible to natural killing even in xenogeneic combinations (*5*). In this report we show that MOLT-4 leukemia cells grow into palpable tumors when these cells are inoculated together with X-irradiated human fibrosarcoma cells into nude mice that have been preirradiated.

MATERIALS AND METHODS

Mice.—BALB/c nude (*nu/nu*) female mice 5-6 weeks old were obtained from Harlan Industries, Madison, Wis. They were kept under sterile conditions in cages with filter bonnets in a laminar flow unit (Lab Products, Rochelle Park, N.J.) and were fed Teklad L-485 sterilized mouse diet and distilled water plus antibiotics and vitamins. For irradiation, mice were placed in 50-ml sterile plastic tubes within their cages and then exposed to 200 rad once a week for 3 weeks.

Cell lines.—The human T-cell leukemia line MOLT-4, established by Minowada et al. (*6*), was grown in suspension culture in RPMI-1640 medium (KC Biologicals, Lenexa, Kans.) supplemented with 5% heat-inactivated FCS. Cells to be injected were taken from culture during the log phase of growth. HT-1080, a human fibrosarcoma cell line established by Rasheed et al. (*7*), was grown in monolayer culture in RPMI-1640 medium containing 5% FCS. HT-1080 cells were stored in liquid nitrogen and were thawed and X-irradiated with 6,000 rad before inoculation into mice.

Injection of tumor cells.—Each mouse received two sc injections, one into each anterolateral side of the thorax. One injection consisted of MOLT-4 cells alone (2×10^4, 2×10^5, or 2×10^6 in 0.2 ml); the other injection consisted of the same numbers of MOLT-4 cells and 2×10^6 X-irradiated (6,000 rad) HT-1080 cells in a total volume of 0.2 ml. Control mice given injections of only X-irradiated HT-1080 cells developed no tumors. We followed local tumor growth by measuring two perpendicular diameters.

Histology.—Five to 6 weeks after tumor cell inoculation, all mice were killed and tissue samples were fixed in B5 fixative (*8*), embedded in paraffin, and stained with hematoxylin and eosin.

Marker studies.—Two T-cell markers were used to determine whether the tumors were comprised of the

LeBien (University of Minnesota) for the MOLT-4 cell line; Dr. L. Furcht (University of Minnesota) for the HT-1080 cell line; Ms. Sandy Johnson (University of Minnesota) for her excellent histologic work; and Dr. Judah Folkmann (Harvard University Medical School) for helpful discussions.

MOLT-4 T-cell leukemia cells. 1) Acid phosphatase staining of imprints from the tumors and of smears from the MOLT-4 tissue culture cell line was done according to the technique of Li et al. (*9*). 2) Single cell suspensions of the tumors were rosetted with SRBC that were treated with *S*-(2-aminoethyl)isothiuronium bromide hydrobromide (AET) as previously described (*10*). Tumor cells with three or more SRBC attached were considered to have formed rosettes.

Statistical analysis.—Tumor incidences were statistically compared with the use of Fisher's exact probability test (*11*).

RESULTS AND DISCUSSION

Inoculation of MOLT-4 leukemia cells alone into nude mice failed to produce tumors in any of 21 recipients. In contrast, a combination of an admixture of MOLT-4 cells with X-irradiated HT-1080 fibrosarcoma cells and X-irradiation of the recipients resulted in tumor development in most nude mice.

The incidence of detectable tumors that developed in mice following inoculation of MOLT-4 cells with X-irradiated (6,000 rad) HT-1080 cells is shown in table 1. In experiment I, terminated 5 weeks after injection of the tumor cells, 2 of 10 mice that had not been X-irradiated developed tumors, whereas 12 of 13 mice that had been X-irradiated with 200 rad at weekly intervals three times before tumor cell inoculation developed tumors. In experiment II, terminated after 6 weeks, 3 of 11 unirradiated mice given injections of MOLT-4 cells plus X-irradiated HT-1080 cells developed tumors, whereas 7 of 12 preirradiated recipients developed tumors. Control mice inoculated with X-irradiated HT-1080 cells alone did not develop tumors. The data from both experiments reveal that the frequency of palpable tumors increased modestly when the MOLT-4 cells were injected with X-irradiated HT-1080 cells as compared to when these cells were injected alone in unirradiated mice (5/21 vs. 0/21, $p<0.01$). The frequency of tumor development in mice inoculated with MOLT-4 cells plus X-irradiated HT-1080 cells was much higher when the recipient mice were preirradiated (5/21 vs. 19/25, $P<0.001$).

Tumors were first detectable 2-3 weeks after transplantation. The sizes of the tumors at the time the mice were killed ranged from 2×2 mm to 17×18 mm with an overall range of 9 mm in diameter in both experiments. The soft tumor was evenly round with a lens shape on the cut sections. The central portion of the tumor often showed a core of fibrous trabeculae, containing capillaries. Small areas of necrosis were often seen in the peripheral portion of the tumor nodule. The predominant cells were lymphoid with fine chromatin and nonconspicuous nucleoli, characteristic of lymphoblastic lymphomas and leukemias (fig. 1). Intermixed with the lymphoid cells were very few large cells (*see arrow* on fig. 1) with abundant eosinophilic cytoplasm always associated with fibrous trabeculae. These cells resembled HT-1080 tumor cells and were probably residual X-irradiated HT-1080 cells that did not proliferate in vivo, since no aggregates of these cells were visible in tumor sections. Further evidence that the tumors which grew were comprised predominantly of the MOLT-4 T-cell leukemia cells derived from the two marker studies. First, acid phosphatase staining revealed polar cytoplasmic staining of the cells from both the subcutaneous tumors and the MOLT-4 cell line. Second, the percentages of cells forming rosettes with SRBC (±SD) were 90±10 in the preparations from 5 separate tumors and 62±5 in 2 samples from the MOLT-4 tissue culture line. HT-1080 fibrosarcoma cells do not form rosettes.

All nude mice from experiment I were examined for evidence of MOLT-4 metastases. No malignant cells were found in any histologic sections of the draining and distant lymph nodes, spleen, bone marrow, pancreas, liver, kidneys, lungs, mediastinum, heart, and brain. Thus, apparently, MOLT-4 cells remain localized and develop into tumors; however, we cannot rule out the possibility that some MOLT-4 cells metastasize but are eliminated before tumor establishment.

The previously reported low success rate for subcutaneous transplantation into nude mice of human

TABLE 1.—*Growth of MOLT-4 leukemia cell-induced tumors in unirradiated versus X-irradiated mice inoculated with MOLT-4 cells and X-irradiated HT-1080 fibrosarcoma cells*[a]

[a] Unirradiated mice or mice X-irradiated with 200 rad three times at weekly intervals were inoculated with the designated No. of MOLT-4 cells together with 2×10^6 X-irradiated (6,000 rad) HT-1080 cells. The same mice were given injections at a distant site with the same No. of MOLT-4 cells alone, and no tumors developed.

[b] Results are expressed as No. of mice with tumors/total No. of mice given MOLT-4 cell injections.

leukemia cell lines or fresh leukemia cells from patients (*2, 3*) might be explained by the fact that leukemia cells produce relatively little AGF as compared with solid tumors (*4*) or by the elimination of circulating leukemia cells by NK cells. Although reports (*2, 3*) have indicated that MOLT-4 leukemia cells can grow sc when many cells are injected, we failed to detect any tumors in 21 mice inoculated with low numbers of MOLT-4 cells alone. On the basis of the observation that X-irradiated cells from solid tumors continue to produce AGF for several weeks (*12*), one explanation for the finding that the X-irradiated HT-1080 fibrosarcoma cells allow MOLT-4 cells to establish as tumors may be that the HT-1080 cells produce AGF; the appearance of large MOLT-4 cell-induced nodules with good vascularization and little necrosis at least supports this contention. A second explanation for this finding is that the fibrosarcoma cells may produce growth factors enabling establishment of MOLT-4 cell-induced tumors. A third explanation is that the fibrosarcoma cells may by some mechanism halt migration of the leukemia cells, thereby decreasing the chance that the leukemia cells would be eliminated by NK cells.

Watanabe et al. (*13*) reported that irradiation of nude mice with 500 rad enabled the growth of iv injected tumor cell lines. Since nude mice have high NK cell activity (*14*) and since many T-cell leukemia cells, including MOLT-4, are sensitive targets for NK cells (*15*), the decrease in NK cell activity occurring after X-irradiation (*16*) might explain the increased tumor frequency. In preliminary experiments we found that spleen cells from unirradiated nude mice caused significant lysis of MOLT-4 cells, whereas spleen cells obtained from mice 1 week after the last of 3 doses of 200 rad of X-irradiation mediated no detectable NK activity against the MOLT-4 target cells.

In summary, our results show that MOLT-4 leukemia cells when inoculated alone did not grow in nude mice, but the incidence of tumor development by these leukemia cells was dramatically increased when the leukemia cells were admixed with X-irradiated fibrosarcoma cells and when the mice were X-irradiated before tumor cell injection. Initial results with freshly isolated human leukemia cells that have not been adapted to tissue culture are encouraging in that it appears that the conditions used in this study to allow establishment of MOLT-4 cell-induced tumors also allow growth of at least some patients' fresh leukemia cells in nude mice. Further studies are required, however, before we can generalize that many, or most, patients' leukemia cells can be established as tumors in nude mice by the procedure we have described.

Although human leukemia is usually characterized by the infiltrative growth of malignant cells in bone marrow and parenchymal organs, growth of leukemias as solid masses is rare (*17*). The growth of human leukemia cells as localized nodules in mice, while not mimicking the disease in humans, may allow assessment of tumor progression and regression by direct measurement of the tumors without invasive techniques; thus it may be a useful model in which to study the effects of various therapeutic modalities on human leukemia, as has been done with human solid tumors (*1, 18*).

Enhanced Expression of Melanoma-Associated Antigens and β_2-Microglobulin on Cultured Human Melanoma Cells by Interferon[1,2]

Shuen-Kuei Liao,[3,4] Pak C. Kwong,[3] Mohammed Khosravi,[3] *and* Peter B. Dent[3,5]

ABSTRACT—The effect of human leukocyte interferon (IFN) on the in vitro growth and expression of melanoma-associated antigens (MAA), β_2-microglobulin (β_2m) and HLA-DR antigen on cultured human melanoma cells was studied. Exposure of melanoma cells to IFN for 64 hours resulted in a dose-dependent inhibition of growth with 46% reduction in cell number at 10^3 U IFN/ml and 74% reduction at 10^5 U/ml. Quantitative absorption experiments in the mixed hemadsorption assay determined that the expression of MAA and β_2m on treated cells was enhanced at 10^2–10^5 U IFN/ml, twofold to fivefold for MAA and fivefold to twelvefold for β_2m. No change was seen in HLA-DR antigen expression. The IFN-induced enhancement of MAA and β_2m could be detected as early as after 16 hours and a maximum expression was reached at 96 hours after IFN exposure. The IFN-induced enhancement of MAA and β_2m on melanoma cells was reversible. Studies with melanoma cells grown in stationary phase and serum-deprived conditions indicated that IFN-induced augmentation of MAA and β_2m did not require cell proliferation. The data suggest that the effect of IFN on antigen expression is independent of its effect on cell growth. Further studies are needed to fully elucidate the mechanism.—JNCI 1982; 68:19-25.

The antiviral agent IFN, thought to be of questionable clinical usefulness for years, has recently shown great promise in the treatment of neoplastic diseases (*1-3*). This substance exhibits a variety of biological effects, which include inhibition of cell proliferation (*4-7*), elevation of cellular enzyme activity (*8*), increase in phagocytosis (*9*), regulation of immune responses (*10-15*), and antitumor effects in experimental animals and man (*16-18*). IFN has also been shown to increase the expression in vitro of a number of cell surface antigens, such as antigens on mouse leukemia cells (*10*), and HLA antigens and β_2m on human lymphoid cells (*19-21*). We have recently described common MAA on cultured and fresh melanoma cells detected by nonhuman primate antisera (*22*). In this report we have shown that human leukocyte IFN enhances the expression of MAA and β_2m on the surface of cultured human melanoma cells as much as fifteenfold to twentyfold. The effect is not due simply to growth inhibition and is reversible upon removal of IFN from the medium.

MATERIALS AND METHODS

IFN.—Human leukocyte IFN, lot P-IF (*23*), was supplied by Dr. K. Cantell, Central Public Health Laboratory, Helsinki, Finland. The titer of this partially purified IFN preparation was 6×10^6 reference U/ml, the specific activity was 4×10^6 reference U/mg of protein. In this paper in referring to the biologically active material as IFN, we recognize the fact that the term refers to a family of different molecules with related properties.

Cells and culture.—Two cell lines, CaCL 73-36 and Daudi, were used. The melanoma line, CaCL 73-36 (*24*), established in our laboratory has been shown to express MAA and HLA-DR antigen as revealed by monkey anti-MAA (*22*) and rabbit-anti-HLA-DR antibodies (Liao S-K, Jerry LM: Unpublished observation). CaCL 73-36 is known to express HLA-A10 on the surface membrane as determined by absorption analysis with HLA-A10 specific alloantibody (*25*). The Daudi lymphoblastoid cell line (*26*), known to be devoid of β_2m and HLA antigens, was obtained from Dr. J. Minowada, Roswell Park Memorial Institute, Buffalo, N.Y.

Melanoma cell line was maintained in monolayer culture in EMEM supplemented with 10% heat-inactivated FCS. The Daudi cells were grown in suspension in RPMI-1640 medium containing 10% FCS. The cultures were incubated at 37°C in a 100% humidified atmosphere of 5% CO_2 and 95% air.

Growth curves.—We seeded 75-cm^2 culture flasks (Falcon Plastics, Los Angeles, Calif.) with 2×10^6 cells in 20 ml EMEM containing 10% FCS. All flasks were incubated at 37°C for up to 7 days without change of medium. Four duplicate flasks were removed from the

incubator every 24 hours. They were rinsed with 0.02% EDTA solution, then trypsinized, and the released cells were counted in a hemacytometer. The results were expressed as the total number of cells per culture.

Antisera.—Anti-CaCL 73-36 raised in an African green monkey (*Cercopithecus aethiops*) by immunizing with the human melanoma line CaCL 73-36, was absorbed with human AB erythrocytes, peripheral blood leukocytes and cells of the oral carcinoma line (KB) to render it melanoma specific (*22*). Anti-β_2m, provided by Dr. J. Gauldie, McMaster University, was raised by immunizing a rabbit with purified human β_2m prepared and donated by Dr. M.D. Poulik, William Beaumont Hospital, Royal Oak, Mich. The immunizing material gave a single precipitating line with the anti-β_2m antiserum but did not react with preimmune serum in Ouchterlony gel diffusion. The anti-β_2m failed to react with the Daudi line but its reactivity was completely removed by four of four B-lymphoid lines as revealed by quantitative absorption analysis. Anti-HLA-DR was supplied by Dr. L.M. Jerry, University of Calgary, Calgary, Canada. This antiserum was produced by immunizing a rabbit with purified human B-lymphocyte glycoprotein and preabsorbed with T-lymphoid cells (Jurkat). The production and immunochemical characterization of this antiserum have been previously described (*27*).

Mixed hemadsorption assay.—This assay was performed as previously described (*25*). The source of sensitizing antisera used in the indicator system depends on the species of origin of the antibody to be detected and the dilution of each antiserum used was previously described (*28*). SRBC sensitized with rabbit or monkey anti-SRBC antiserum, followed by a second sensitization with sheep anti-rabbit IgG or sheep anti-human IgG, are effective for the detection of rabbit or monkey, (human) antibodies, respectively. Monkey and human reagents can be used interchangeably because of the antigenic cross-reactivity of their immunoglobulins.

Quantitative absorption technique.—To quantitate changes in cell surface antigen content, we followed the principles previously reported by Boyse et al. (*29*). The quantitative absorption test was done with the use of a concentration of antiserum, two doubling dilutions higher than that which gave 50% positivity in antibody titration. Antiserum in 100-μl aliquots was absorbed with increasing numbers of treated or untreated cells by gentle rotation of the microtubes containing cells and serum at room temperature for 1 hour. The microtubes were subsequently kept at 4°C overnight. Sera were collected by centrifugation at 3,000×g for 3 minutes in a microcentrifuge (model 59, Fisher Scientific, Montreal, Canada). Absorbed and unabsorbed sera were then assayed by mixed hemadsorption with use of the appropriate reference cell line.

The percentage of inhibition of antiserum reactivity relative to the unabsorbed antiserum control was plotted on an arithmetic scale against the number of cells used for absorption on a logarithmic scale. The number of cells required for 50% inhibition of binding activity by antiserum (AD_{50}) was calculated from the inhibition curve. The absorptive capacity of the IFN-treated group was expressed in relation to the untreated control group by means of the formula: AI = AD_{50} of untreated group/AD_{50} of treated group.

RESULTS

Effect of Different Concentrations of IFN on In Vitro Growth and Surface Antigen Expression

Table 1 shows the effect of various IFN concentrations on melanoma cells grown for a period of 64 hours. Treatment of the CaCL 73-36 melanoma cells with IFN resulted in a dose-dependent growth inhibition, with a 45.5% reduction in cell number at 10^3 U IFN/ml and 73.6% reduction at 10^5 U IFN/ml, compared to the untreated control cells. Expression of MAA and β_2m on the treated cells was enhanced at all IFN concentrations, 1.7- to 4.8-fold for MAA and 4.6- to 12.4-fold for β_2m. No enhancement of HLA-DR expression was observed following IFN exposure for 64 hours (table 1) or for 168 hours (stationary phase, data not shown).

Since there was a diminution in the rate of increase of antigen expression as well as cell growth with IFN concentrations higher than 10^3 U/ml, in subsequent experiments 10^3 U/ml was employed.

In text-figure 1 results of a representative experiment show the effect of 10^3 U IFN/ml on the growth curve of melanoma cells over a 7-day culture period. There was an initial prolongation of the lag phase, but by day 4 the IFN-treated cells reached a saturation density equal to that of the untreated cells. Over the next 24 hours a 50% decrease in cell numbers occurred in the IFN-treated cultures due to detachment of dead cells as determined by trypan blue dye exclusion test.

No differences could be detected in the cellular morphology between control and IFN-treated melanoma cells by light microscopy. This melanoma cell line is grossly amelanotic, and no obvious pigmenta-

tion was induced by IFN treatment as judged by the color of the cell pellets.

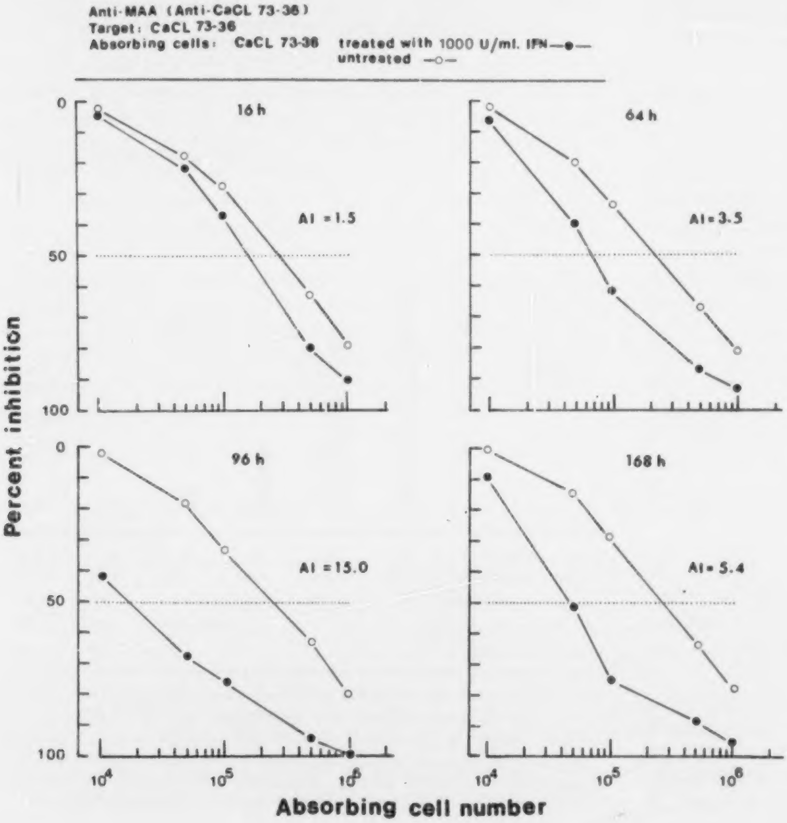
Kinetics of Enhancement by IFN of MAA and β^2m Expression

A time course study was performed to determine the effect of 10^3 U IFN/ml on the expression of MAA. The expression of MAA on melanoma cells at different times after the initiation of culture was determined by quantitative absorption experiments with the use of an anti-MAA antibody. Results of a representative experiment (text-fig. 2) show that AI for the IFN-treated groups at 16, 64, 96, and 168 hours are 1.5, 3.5, 15.0, and 5.4, respectively. It is clear that an increase in MAA expression could be detected as early as 16 hours after IFN-exposure, and maximal expression of MAA on the treated cells was reached at 96 hours. The untreated melanoma cells did not change in their MAA expression during the culture period from 16 through 168 hours.

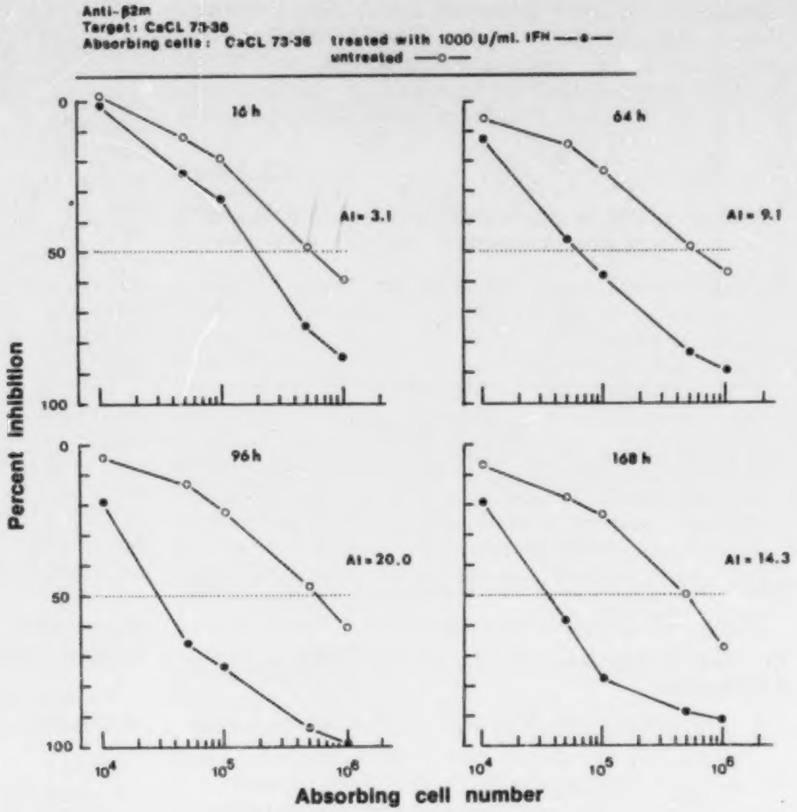
Text-figure 3 shows the effect of IFN on β_2m expression by the melanoma cells in the same time course experiment described above. Enhanced expression of β_2m was first detectable at 16 hours and the AI value was 3.1. The AI progressively rose to a maximum of 20.0 at 96 hours and declined to 14.3 at 168 hours. No changes were seen in β_2m expression on the untreated cells over the 168-hour culture period.

Reversibility of IFN-Induced Enhancement of Antigen Expression

To determine whether the effect of IFN treatment on MAA and β_2m expression was reversible, the following



TEXT-FIGURE 2.—Kinetics of enhanced MAA expression by IFN-treated melanoma cells as determined by quantitative absorption. 2×10^6 cells were cultured in 75-cm² flasks in 20 ml medium.



TEXT-FIGURE 3.—Kinetics of enhanced β_2m expression by IFN-treated melanoma cells as determined by quantitative absorption. 2×10^6 cells were cultured in 75-cm^2 flasks in 20 ml medium.

experiment was performed (text-fig. 4). Melanoma cells were grown in medium containing 10^3 U IFN/ml for 96 hours and then divided into 5 groups: Group 1) cultures were terminated at this point; Group 2) cultures were allowed to continue for a further 48 hours after replacement of medium with fresh medium containing 10^3 U IFN/ml; Group 3) cultures were allowed to continue for a further 48 hours after replacement of medium with fresh medium without IFN; Group 4) cultures were allowed to continue for a further 96 hours after replacement of medium with fresh medium without IFN; Group 5) cultures were allowed to continue for a further 144 hours after replacement of medium with fresh medium without IFN. In a sixth group, melanoma cells were initially grown in medium without IFN for 96 hours and then allowed to continue for a further 144 hours after replacement of medium with fresh medium without IFN. In a last group, melanoma cells were grown in medium without IFN for 96 hours. The cells harvested from each group were analyzed by quantitative absorption with anti-MAA and anti-β_2m antibodies for surface antigen content.

Relative antigen content of melanoma cells in groups 1 to 6 was determined by AI value, which was obtained by dividing AD$_{50}$ of the last group (cells grown for 96 hours in IFN-free medium) by AD$_{50}$ of each experimental group. As can be seen in text-figure 4, removal of IFN from the culture medium (groups 3, 4, and 5) resulted in significant reduction in MAA and β_2m expression as compared to group 1 or 2. After 144 hours of incubation in IFN-free medium, the antigen

Relative antigen content of each group was reflected by AI value, which was expressed in relation to the melanoma cells grown in medium without IFN for 96 hr. *See* text for experimental details.

level was reduced to the basal content of the antigens expressed on the untreated melanoma cells.

Enhancement by IFN of MAA and β_2m in Stationary Cultures of Melanoma Cells

To determine whether IFN would enhance expression of MAA and β_2m by melanoma cells in stationary cultures, we grew melanoma cells in EMEM containing 10% FCS for 96 hours, by which time stationary phase was reached (text-fig. 1). This was followed by replacement of spent medium with serum-free EMEM and further incubation for 72 hours. At this point two experimental groups were established: In group 1, cultures were allowed to continue for a further 64 hours with or without addition of 10^3 U IFN/ml after replacement of exhausted medium with fresh, but serum-deprived medium; In group 2, cultures were allowed to continue for a further 64 hours with and without addition of 10^3 U IFN/ml after replacement of exhausted medium with fresh medium containing 10% FCS. The harvested cells from each group were used for quantitative absorption with anti-MAA and anti-β_2m antibodies for determination of antigen content. As can be seen in table 2, the expression of MAA and β_2m by stationary phase melanoma cells was enhanced by IFN treatment. The addition of FCS during the period of IFN exposure was not necessary for the enhancement, although the degree of β_2m expression appeared greater in the presence of added FCS. These data suggest that enhancement of expression of these two antigens by IFN does not require cell growth.

Control Experiments

To exclude the possibility that IFN nonspecifically induces neoantigens or promotes expression of cryptic antigens, Daudi lymphoid cells known to be free of MAA and β_2m were incubated with and without IFN for 64 and 96 hours. When the cells were tested for expression of these two antigens by quantitative absorption with anti-MAA and anti-β_2m antibodies, reduction of antibody reactivity was not seen in either instance (data not shown).

DISCUSSION

In this study we demonstrated that human leukocyte IFN enhances the expression of MAA and β_2m in cultured human melanoma cells. Previous studies have documented increased expression of β_2m (*19, 21*) and histocompatibility antigens (*10, 19, 20, 30-33*) on both murine and human lymphoid cells; however, this is the first demonstration of a similar phenomenon on nonlymphoid tumor cells. The effect is more marked with β_2m, although the qualitative aspects of enhanced MAA and β_2m expression are similar, such as dose response, kinetics and reversibility. We have shown that there is a dose-dependent enhancement of MAA and β_2m by IFN and that the effect can be detected as early as 16 hours after addition of IFN to the cultures. The enhancement is maximal at 96 hours and then declines somewhat by 168 hours. This decline could be due to depletion of IFN in the medium inasmuch as an addition of fresh IFN at 96 hours appears to sustain the effect (table 2). Alternatively or additionally, antigen-rich cells may selectively detach from the culture flask as can be seen by the decrease in cell numbers observed after 96 hours. The specificity of the effect can be seen from the absence of concomitant enhancement of HLA-DR expression and the lack of appearance of β_2m or MAA on Daudi cells which normally do not express the antigens.

The enhancing effect of IFN on antigen expression by melanoma cells was also seen on two additional melanoma cell lines and is therefore not a unique finding for the CaCL 73-36 cell line. We are currently examining a panel of melanoma cell lines representative of a spectrum of MAA expression to explore the relationship of the degree of IFN-induced enhancement to the basal antigen concentration. Using hybridoma antibodies, we have recently described a common fetal neuroectodermal antigen of melanoma, neuroblastoma, retinoblastoma, glioma, and fetal brain cells (*34*). IFN treatment induces a fourfold enhancement of the expression of this antigen on melanoma cells (data not shown).

Although we have not determined the exact mechanism of action of IFN in antigen enhancement, we have considered the possibility that IFN selectively suppresses the proliferation of cells that are antigen-

[b] No detached cells observed at the termination of culture.

deficient, permitting the outgrowth of a population of antigen-rich cells. This is, however, unlikely because enhanced antigen expression occurs in cells that are not growing (table 2), as well as in cells that are in lag phase of growth (text-figs. 1 and 2). The fact that enhancement is reversible argues against selective population deletion. Finally analysis of IFN-treated human lymphoid cells for β_2m expression using the fluorescence activated cell sorter showed a homogeneous alteration of distribution of staining intensity rather than the appearance of two cell populations (*19*). A similar result was obtained with the expression of H-2 antigens on IFN-treated murine lymphoma cells (*35*). We conclude, therefore, that elimination of an antigen-deficient population of cells does not explain the phenomenon. Alternatively, IFN treatment may result in a decreased turnover of cell surface antigens and/or stimulation of antigen synthesis.

The observations of Chang et al. (*36, 37*) suggest that the changes observed in IFN-treated cell membranes are general changes; however, there is a definite selectivity in what sorts of antigen show enhanced expression. Histocompatibility antigens (*19, 20, 30–32*), β_2m (*19, 21*) and MAA are enhanced whereas HLA-DR (*20, 21, 29*) Thy-1 (*31*), human T-antigen (*19*), surface IgG and IgM (*19, 30*) and Fc receptor (*30*) expression are not affected. It is not immediately clear what property or characteristic of a surface antigen determines its enhanceability by IFN. Nevertheless, it is of interest that none of the nonenhanced structures are β_2m related while HLA and H-2 antigens are β_2m associated. We (*38*) and others (*39, 40*) have evidence suggesting an association of β_2m with MAA, although there is also evidence to the contrary (*41, 42*).

We conclude that growth inhibition alone does not account for enhanced antigen expression since the enhancement was seen in cells that were fully confluent and serum starved (table 2). A similar conclusion regarding the independence of antigen enhancement and cellular proliferation was reached by Killander et al. (*35*) who performed simultaneous single cell analysis of H-2 antigen expression, DNA content, dry cell mass, and [^{3}H]thymidine uptake of IFN-treated leukemia cells.

Finally, it is tempting to speculate that enhancement of tumor antigenicity by IFN may be an important mechanism to explain the antitumor effects of IFN (*3, 16*). One could envisage that IFN-treated antigen-enriched cells might be more immunogenic and, at the same time, more susceptible to immune attack.

In Vitro Reversal of Depressed T-Lymphocyte Function in the Peripheral Blood of Brain Tumor Patients[1, 2]

Gary W. Wood[3] *and* **Robert A. Morantz**[4]

ABSTRACT—Peripheral blood mononuclear cells from some brain tumor patients exhibited depressed T-lymphocyte responses to the polyclonal mitogen phytohemagglutinin (PHA). These responses, initially depressed, were restored to near normal by a 24-hour preculture in growth medium. The effect of preculture was mimicked by mild trypsinization before addition of PHA. In addition, cells treated with deaggregated antihuman IgG resulted in greatly reduced responses to mitogen by mononuclear cells from all brain tumor patients. Anti-IgG had no effect if cells were precultured for 24 hours. The results suggest that, in brain tumor patients, depressed immune function associated with tumor progression was caused by suppressor cells which were activated by humoral factors that express IgG antigenic determinants.—JNCI 1982; 68:27-33.

Depressed peripheral T-lymphocyte function in patients with cancers is well established. In general, the existence and magnitude of depressed responses correlate well with advanced disease (*1*). That observation indicates that immunodepression is secondary to interaction between tumor and host. Although the precise role of tumor immunity in limiting or promoting tumor spread is unknown, there is considerable evidence that progressive tumor growth is linked to the functional integrity of the immune system.

A high proportion of patients with tumors of the CNS exhibit compromised peripheral immune function (*2-4*). Because these patients present initially in a depressed functional state, they serve as an excellent model system for studying responsible mechanisms. Early studies of CNS tumor patients' cells demonstrated that depressed function was at least partially produced by a serum factor that co-purified with IgG (*2, 3*). The mechanism whereby such serum factors may be functioning remains to be elucidated. The situation is further complicated by the observation that a high proportion of CNS patients exhibit depressed T-cell function in the absence of autologous serum, a suggestion that nonhumoral suppressor factors are present [Wood GW, Morantz RA: Unpublished observations, (*2*)]. The possibility has been considered that CNS tumor patients may also have high levels of circulating suppressor cells.

Several recent studies have demonstrated that peripheral blood monocytes can function as suppressor cells in cancer patients (*5-7*). Therefore, a previous study (Wood GW, Morantz RA: Submitted for publication) was undertaken in this laboratory to determine if monocytes were exerting suppressor function in CNS tumor patients. We established that in most patients immune depression was related to monocytosis and that monocytes functioned as suppressors. Nevertheless, all depressed function was not due to monocyte activity (Wood GW, Morantz RA: Unpublished observations). At least two mechanisms appear to be involved, one humoral and the other cellular, although other possibilities have yet to be evaluated.

The present study was designed to probe the possibility that a unified theory might explain the previous results. Many of the findings can be explained by postulating that circulating suppressor factors function by activating suppressor cells rather than by directly inhibiting T-lymphocyte differentiation. Thus suppression would occur in vitro in the presence of humoral factors but could also occur when such factors were not included in the culture system. This last effect would be observed if suppressor cells remained activated for significant periods of time in vitro or if a sufficiently high concentration of suppressor factors remained bound to the cells when they were removed from the in vivo milieu. Thus factor-induced suppression could be maintained in vitro in the absence of autologous serum. Such a possibility is supported by the observation that depressed T-cell responses can be reversed by extensively washing the cells or by culturing the cells for 24-48 hours before adding the mitogen (*8-11*). Thus removal of the in vivo adsorbed suppressor factors from the surface of cells appears to result in enhanced responses (*8-11*). Further support for the theorized mechanism is provided by the fact that antigen-antibody complexes, which function as blocking factors, have been eluted from peripheral blood leukocytes of cancer patients (*12*). If the cells to which suppressor factors were adsorbed include monocytes, then the possibility of a common mechanism is increased, because monocytes are the major circulating suppressor cells that have been described in cancer patients.

ABBREVIATIONS USED: CNS=central nervous system; FBS=fetal bovine serum; HBSS=Hanks' balanced salt solution; [^{3}H]dThd=tritiated thymidine; MEM=minimum essential medium; PHA=phytohemagglutinin.

MATERIALS AND METHODS

Patients.—Of 47 patients with CNS tumors, 8 had glioblastomas, 7 had astrocytomas, 4 had meningiomas, 2 had oligodendrogliomas, 14 had an assortment of other primary tumors of the CNS, and 12 had tumors metastatic to the brain from other sites. All patients were studied before their tumors were surgically removed and were receiving neither radiotherapy nor chemotherapy. Healthy adults were included as controls for the separation procedures, cell enumerations, and T-cell function studies.

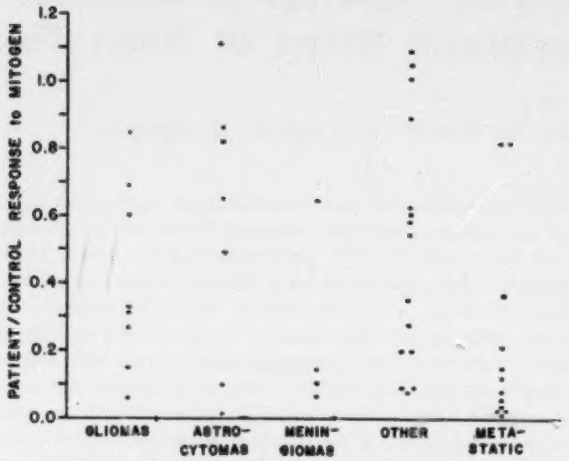
Mononuclear cell isolation.—Peripheral venous blood was drawn into Vacutainer tubes containing 250 U of preservative-free heparin. Mononuclear cells were isolated by Ficoll-Hypaque density gradient sedimentation, washed twice with HBSS, and suspended in Eagle's MEM supplemented with 15% FBS, 100 μg streptomycin/ml, and 100 U penicillin/ml. Cell populations obtained were evaluated without further modification.

Monocyte depletion.—Mononuclear phagocytes were selectively removed from mononuclear cell suspensions by glass adherence. After 3 ml of growth medium containing $3\text{-}5\times10^6$ cells/ml were added to sterile glass slides, the cells were allowed to adhere for 30 minutes at 37°C. Nonadherent cells were washed from the slides with HBSS and readhered under identical conditions. The final population of nonadherent cells was counted, cytocentrifuged, and stained with Wright's agent. The effectiveness of adherent cell removal was determined by counting the percentage of morphologically identifiable monocytes.

Mitogen stimulation.—A suspension of 5×10^4 mononuclear cells in 0.2 ml of MEM plus 15% FBS was added to each well of a Linbro 96-well flat-bottomed Disposotray. PHA-M (GIBCO, Grand Island, N.Y.) at three concentrations (1, 5, and 10 μl of stock PHA-M/ml) was added to each well. Six replicates were performed for each mitogen concentration as well as for the cell control. Cells were cultured in 5% CO_2 in a humidified incubator at 37°C. After a 72-hour incubation, 12.5 μCi of [^{3}H]dThd was added to each well and the culture was continued for 18 hours. Samples were harvested on glass-fiber filters with an automated cell harvester, solubilized, and counted in a Mark III beta-scintillation counter.

Preculture.—Cells were added to wells as described above, but mitogen was omitted. Plates containing cells in growth medium were incubated under the described culture conditions for 24 hours. Mitogen was added to unchanged medium. The cultures were continued for the prescribed post-mitogen period, i.e., 72 hours in the presence of PHA-M and an additional 18 hours with [^{3}H]dThd as described above.

Enzyme treatment.—From density gradient sedimentation, 5×10^6 mononuclear cells were obtained and washed as described, were suspended in 5 ml of 0.25% trypsin, and were incubated for 15 minutes at 37°C and washed twice with HBSS. Trypsinized cells were then tested for mitogen responsiveness as described above.



TEXT-FIGURE 1.—Mitogenic responses to PHA by T-lymphocytes from CNS tumor patients. Data are presented as ratios of maximum patient responses to maximum control responses.

Statistics.—Because all analyses involved demonstration of differences between paired samples, Student's *t*-test was used to determine significance.

RESULTS

Depressed mitogen responsiveness.—More than 50% of mononuclear cell samples from CNS tumor patients exhibited depressed T-lymphocyte mitogen responsiveness (text-fig. 1). Depressed responses were identified by comparison of the maximum response of the patient's mononuclear cells to the maximum response of a healthy individual's mononuclear cells on the same day. The values were expressed as ratios (the maximum mean patient response divided by the maximum mean control response). We have arbitrarily defined depressed responses as those producing a ratio of 0.5 or less. The normal response range from this laboratory has been reported previously (*13*).

Effect of preculture on normal mitogen responses of mononuclear cells.—The present experiments were designed to determine whether depressed mitogen responses could be reversed by a 24-hour preculture. Precultured control cells previously showed enhanced mitogen responsiveness (*14*), and similar results were obtained in the present study. A 24-hour preculture generally produced a significantly enhanced [^{3}H]dThd uptake (table 1, $P<0.005$).

Although the apparent effect of preculture was an overall increase in responsiveness, there was some concern that preculture simply altered the response profile. Maximum mitogen response was usually observed after 72-96 hours of culture, but evaluation of the possibility that artifacts were induced by preculture was needed. We found that peak responses to PHA for control cells occurred between 72 and 96 hours; peak responses for 24-hour precultured cells also occurred at 72-96 hours. Although there was no significant shift of the response peak, enhanced responsiveness produced

[a] Mononuclear cells were precultured for 24 hr at 37°C in the absence of mitogen.

[b] Cells were cultured for 72 hr in the presence of PHA. [^{3}H]dThd was added and responses were measured after 18 hr. Only maximum responses are listed.

by preculture was frequently greater after 48 hours than after 72 or 96 hours of culture.

We were also concerned that preculture could shift the mitogen concentration optimum. Extensive titration of mitogen demonstrated that lower or higher PHA concentrations consistently resulted in reduced responses, i.e., optimum mitogen concentrations were used throughout the study. Therefore, preculture appeared to produce an objective increase in mitogen responses of mononuclear cells from healthy individuals.

Effect of preculture on mitogen responses of patients' mononuclear cells.—Patient responses to PHA were divided: Some responses were normal and some were depressed. Patients whose responses were defined as depressed gave a maximum response that was less than 50% of the maximum response of control cells. The effect of preculture on cells from patients in the nondepressed group is summarized in table 2. As was seen with control cells, preculture produced a consistent increase in responsiveness ($P<0.05$). The mean increase for this group of patients was nearly identical to that of the control cells. However, the variance was greater. Responses were suppressed in 2 patients and were more than doubled in another 2. These results suggest that some of the patients in the group with arbitrarily defined "normal" responses actually had moderately depressed T-lymphocyte function. The major value of the studies of the effects of preculture on normal responses was to demonstrate that preculture had no apparent negative effects on mononuclear cells and that enhancement of nondepressed responses was minimal.

The effect of preculture on cells from CNS tumor patients with depressed responses to mitogen also is presented in table 3. In each case there was a highly significant ($P<0.0005$) enhancement of mitogen responsiveness subsequent to preculture. Responses were at least doubled in all cases, bringing more than one-half of them within the normal range. Although responses that initially had been severely depressed were enhanced by preculture, they remained subnormal.

The possibility was considered that the depressed responses observed were an artifact of the culture system. Perhaps cells from these patients exhibited maximum proliferation within a different time frame. However, we found that depressed responses were observed whether cultures were terminated after 24, 48, 72, 96, or 120 hours; maximum response was again obtained between 72 and 96 hours.

[a] Mononuclear cells were precultured for 24 hr at 37°C in the absence of mitogen.

[b] Cells were cultured for 72 hr in the presence of PHA. [^{3}H]dThd was added and responses were measured after 18 hr. Only maximum responses are listed.

Comparison of the effects of preculture and adherent cell removal.—In previous studies (*5-8*), the possibility was explored that monocytes functioned as suppressor cells. We observed that T-cell dysfunction could be partially reversed by removal of adherent cells (Wood GW, Morantz RA: Unpublished observations). We therefore evaluated the relative benefits of preculture and adherent cell removal by manipulating the adherent fraction of mononuclear cells from several patients, and we present the data in table 4. In all cases, preculture reversed the depressed lymphocyte function, whereas adherent cell removal was not always effective. In table 4, the patients are divided into 2 groups, one in which adherent cell removal resulted in significantly improved responses ($P<0.05$) to PHA, and the other in which the responses were not enhanced. In fact, the responses were depressed further. The effect of preculture on these 2 groups was highly significant ($P<0.005$). These experiments do not establish whether common or different mechanisms were involved. However, when total reversal of the functional defect was obtained by preculture, adherent cell removal sometimes also produced partial reversal, suggesting that the two events may be related.

Effect of trypsinization on mononuclear cell mitogen responsiveness.—If one of the possible effects of preculture is to allow either the death or the destruction of suppressor cells, then it should not be possible to reconstitute T-cell function by stripping proteins from the cell membrane immediately before culture. To test this hypothesis, we briefly exposed mononuclear cells to trypsin, then cultured the treated cells in the presence of mitogen. The results obtained for cells from healthy individuals and from CNS tumor patients with nondepressed responses are summarized in table 5. Treatment of normal cells with trypsin did not appreciably affect responsiveness to mitogen; the cells were viable and apparently capable of interacting with mitogen. In contrast, when cells from patients with depressed responses were similarly treated, a significant ($P<0.05$) augmentation of responses was observed (table 6). Trypsinization and preculture had similar effects on mitogenic responses. These results suggest that a major proportion of depressed T-lymphocyte function in brain tumor patients was produced by a cell surface-associated factor.

TABLE 4.—*Mononuclear leukocytes from CNS tumor patients: Ability of monocyte depletion and preculture to reconstitute depressed PHA responses*[a]

Mononuclear cell response to PHA, cpm ± SD			Ratio of untreated to:

[a] After a 15-min incubation at 37°C in 0.25% trypsin, mononuclear cells were washed and cultured with PHA.

Effect of rabbit anti-human IgG on mitogen responses.—Previous studies of depressed T-cell function in brain tumor patients have implicated IgG as a humoral suppressor factor (*2, 3*). The suppressive IgG could theoretically be in several forms which include antigen-antibody complexes, antilymphocyte antibodies, and immunoglobulin fragments. Because previous experiments suggested that membrane-associated factors were responsible for T-cell dysfunction and because circulating IgG-associated factors are known to have immunosuppressive effects in brain tumor patients, the important determination was whether some part of the membrane-associated events might be related to IgG. We theorized that if membrane-associated IgG was causing the suppression, then introduction of specific anti-IgG to the culture system might enhance the effect. In fact, each time anti-IgG was either bound to cells before culture or added to the cultured cells, depressed responses were further depressed (data not shown). Anti-IgG not only futher depressed already depressed responses but also produced a profound suppression of responses by cells from patients with

initially normal responses (table 7). The effect of anti-IgG on PHA responses of cells from healthy individuals was not specifically suppressed. Normal rabbit serum sometimes suppressed responses, but not to the degree that the rabbit anti-human IgG did.

The effect of anti-IgG on precultured cells also was tested. The results in table 8 clearly demonstrate that, whereas reacting cells with anti-IgG before preculture caused suppression of mitogenesis, the combination of anti-IgG with preculture had no comparable effect.

DISCUSSION

Progression of tumors is thought to be facilitated by blocking factors, possibly antigen-antibody complexes, which interfere with cell-mediated cytotoxicity by as yet undefined mechanisms (*15*). Although most experimentation has focused on specific blocking of T-cell-mediated tumor cell destruction, Gorczynski et al. (*16*) have also suggested that antigen-antibody complexes may have a nonspecific immunoregulatory role. It is known that "blocking factors" eluted from tumors function nonspecifically as well as specifically (*17*). Despite these observations, few attempts have been made to link blocking phenomena with the generalized nonspecific immune depression that often is seen in association with neoplasia. Similarly and interestingly, brain tumor patients have circulating factors that are IgG in nature, i.e., either antibody or antigen-antibody complexes, which nonspecifically suppress immune function (*2, 3*), and they have blocking factors that inhibit T-cell-mediated cytotoxicity (*18*).

The present study was based on the assumption that depressed responses to T-lymphocyte mitogens, which are seen with mononuclear cells from brain tumor patients, are real phenomena and was designed to explore possible mechanisms. Our culture conditions did not include autologous serum so that initially we could evaluate the possible presence of suppressor cells. Extensive studies established that most patients with depressed responses exhibited evidence for the presence of suppressor cells, principally monocytes (Wood GW, Morantz RA: Unpublished observations). Those observations were essentially confirmatory of previous studies

demonstrating monocyte suppressors in patients with various types of cancer. Representative results are included here. The importance is that, although responses to mitogen were improved by removal of adherent cells, responses rarely returned to normal. Moreover, our preculture and trypsinization results strongly suggest an even more complex situation. Both preculture of mononuclear cells for 24 hours and trypsinization of mononuclear cells for 15 minutes generally produced an almost complete reconstitution of T-cell function, at least as determined by responsiveness to a polyclonal mitogen.

These results are important for three reasons. First, they establish that depressed T-cell function is a real rather than a statistical phenomenon. That is, relatively trivial manipulations of the cells allow them to respond in the normal range. The responses weren't low just because the control for that day happened to give a high response or just because the number of T-cells present was too low. Second, the results suggest that some type of control mechanism is involved rather than an inherent T-cell defect. Third, the return of responsiveness with preculture could be explained by loss of suppressor cells, but the trypsinization results suggest that some alternative explanation must be sought. The results of trypsinization are difficult to explain in any other way than by removal of cell-associated factors. Viability was not lost during trypsinization, and trypsinization had no appreciable effect on normal cells. This interpretation is totally consistent with previous observations that brain tumor patients have circulating soluble suppressor factors (*2, 3*). Moreover, the results are consistent with previous reports in humans and experimental animals which demonstrated that extensive washing (*8*), preculture (*9, 10*), or trypsinization (*11*) of cells could bring about enhanced immune responsiveness. Of course, all of these observations only demonstrate that if there are humoral immunosuppressive factors their ultimate effect must be on or through cells. It does not tell us what cell types are affected.

There are two major explanations for the immunodepression: suppressor cells and soluble immunoregulatory factors. The results of the present study clearly demonstrate that suppressor cells and suppressor factors coexist in the same patient. One might be able to explain this by saying that each independently contributes to the depression. However, as was mentioned earlier, humoral factors must either act directly on the T-cells or act indirectly through accessory cells. Because suppressor cells clearly were present, but depression often was completely reversed by removal of cell-associated factors, we hypothesize that the circulating factors act by stimulating suppressor cells, i.e., there is no inherent suppressor cell defect. However, the results of the present study do not prove that this is the situation. The alternative that the factors act directly on T-cells remains viable.

The precise nature of the humoral factors involved is an open question. Clearly, the fact that previous studies demonstrated IgG suppressor factors would suggest antibodies or antigen-antibody complexes as prime candidates. Moreover, a previous study in which peripheral blood cells from patients with differnt types of cancer were used also implicated membrane-associated antigen-antibody complexes in the depression (*13*). Those results are further supported by the preliminary results obtained in the present study. Highly specific anti-IgG consistently produced profound depression of responses to PHA. Although some depression was produced also by normal rabbit serum, it was not comparable. The fact that the inhibitory effect of anti-IgG is lost subsequent to preincubation clearly supports the concept that a surface-associated IgG factor is associated with the suppression.

The results of the present study support the idea that tumor-associated nonspecific T-lymphocyte dysfunction is produced by membrane-associated suppressor factors, which appear to be IgG in nature. Clearly, much more work must be done before the nature of these factors and the cells to which they are adsorbed has been established. However, our results are consistent with previous observations that antigen-antibody complexes are capable of inducing profound immunosuppression through an Fc-dependent mechanism. This mechanism would explain the reversal of immunodepression by washing, trypsinization, or preculture (endocytosis or shedding of surface-associated Ig) and would explain the enhanced depression induced by anti-IgG. The model that appears most consistent with the various observations is that circulating, soluble antigen-antibody complexes bind to the surfaces of Fc receptor-positive cells, including monocytes, which are induced to suppress the T-cell responses. Again, we emphasize that the present results do not prove this mechanism; they only suggest that further work is necessary.

Human Adherent Cell Contact-Mediated Modulation of Normal Myeloid Colony Formation[1,2,3]

ABSTRACT—The effects of coincubation of normal nonadherent bone marrow cells on adherent monolayers created from human peripheral blood mononuclear cells or marrow cells were investigated. Nonadherent marrow cells were coincubated for 4 hours with peripheral blood adherent cells at ratios of adherent cells to marrow cells of 2:1 to 5:1. This coincubation suppressed subsequent neutrophilic agar colony growth but not eosinophilic growth. Further studies suggested that this suppression was a cell-cell-mediated process and not secondary to soluble factors. However, coincubation on marrow adherent cells caused increased neutrophilic colony recovery. The possible in vivo relevance is discussed.—JNCI 1982; 68:35–42.

Adherent cells, probably monocytes, have been reported to have many regulatory influences on the clonal growth of human hematopoietic progenitor cells. Monocytes incorporated into agar cultures have been shown to have both stimulatory effects on myeloid CFU-C secondary to CSA release and inhibitory effects when in high numbers secondary to PGE_2 release (*1–3*). Monocytes from peripheral blood have been reported to inhibit erythroid colony growth (*4*), but those from bone marrow stimulate such growth (*5*). We have described inhibitory effects of bone marrow adherent cells from leukemia marrow on leukemia growth (*6*). However, those experiments incorporated adherent cells in differing numbers directly into the agar, an experimental situation in which cells are relatively immobilized and which does not allow significant cell-cell contact.

More recently, we demonstrated that peripheral blood cells from normal donors could inhibit leukemia clonogenic cells (*7*). This inhibition required only brief cell-cell contact and could not be reproduced by the same number of cells when incorporated into agar but separated from the marrow target. We next investigated the question of whether such inhibition was specific to leukemia clonogenic cells. This article describes experiments showing similar inhibition of normal GM-CFC by peripheral blood adherent cells. The possible in vivo relevance to hematopoietic control and the microenvironment is discussed.

MATERIALS AND METHODS

Acquisition of specimen.—Peripheral blood, a source of $M\phi$, was obtained by venipuncture from normal human volunteers. The marrow cells used were obtained by posterior iliac crest puncture from lung cancer patients under local anesthesia and without any hematologic abnormalities. Before acquiring any specimens for experimentation, we obtained a signed written consent from each patient as required by the Surveillance Committee on Human Experimentation at The University of Texas System Cancer Center, M. D. Anderson Hospital and Tumor Institute. The specimens were collected in polystyrene tubes (Corning Glass Works, Corning, N.Y.) containing 0.3-ml preservative-free heparin (100 U/ml) in 1.7 ml PBS.

Cell separation procedures.—T-lymphocytes: To obtain mononuclear cells, we diluted peripheral blood in an equal volume of α-MEM plus 15% FCS and centrifuged the mixture at 400×g for 35 minutes over Ficoll-Hypaque columns (density, 1.077 g/ml) in 15-ml plastic tubes. To separate T-cells, we used a modification of the method described by Weiner et al. (*8*) in which a 1-ml 5% sheep erythrocyte suspension was incubated for 1 hour at 37°C in a neuraminidase solution at a final concentration of 17 U/ml and then washed three times with α-MEM. Subsequently, the mononuclear cells or low-density nonadherent marrow cells were incubated with NE as described (*8*), and the NE rosettes were pelleted by centrifugation over a Ficoll-Hypaque column (density, 1.080 g/ml). The NE in the pellet were lysed with Tris buffer, and the remaining cells were subjected to carbonyl iron phagocytosis and plastic adherence procedures to remove contaminating phagocytic and adherent cell populations. This preparation contained 99% rosetting cells.

ABBREVIATIONS USED: CFU-C = colony-forming unit(s)—culture; CSA = colony-stimulating activity; FCS = fetal calf serum; GM-CFC = granulocyte-macrophage colony-forming cells; HPCM = human placental conditioned medium; $M\phi$ = monocyte-macrophage; α-MEM = alpha modification of minimum essential medium; NE = neuraminidase-treated erythrocyte(s); PBS = phosphate-buffered saline; PGE_2 = prostaglandin.

The T-cell-depleted population contained 1% or less T-cells.

Mϕ: Mononuclear cells in a 2-ml total volume ($2\text{-}4\times10^6$/ml), in some cases T-cell depleted, were subjected to active adherence by incubation for 3 hours in α-MEM in the presence of 20% FCS at 37°C in a 5% CO_2 atmosphere. Subsequently, the nonadherent cells contained in the supernatant were aspirated and the dishes were washed twice with α-MEM plus 15% FCS. We determined the number of adherent cells remaining in the dish by subtracting the number of nonadherent cells per dish (the total number of nucleated cells in the supernatant and washes) from the total number of cells per dish subjected to the adherence procedure. This number of remaining adherent cells correlated with the predicted number of adherent cells based on the percentage of latex-phagocytosing cells in the interface cells.

Low-density nonadherent marrow cells: Low-density nonadherent bone marrow cells for coincubation assays were obtained as described elsewhere (*9*). Low-density cells (<1.078 g/ml) obtained by Ficoll-Hypaque gradient centrifugation were subjected to the plastic adherence procedure described above. Subsequently, the nonadherent cells were aspirated, washed once, and resuspended in α-MEM plus 15% FCS at a cell concentration of approximately 10^6/ml.

Coincubation of nonadherent normal marrow cells with the adherent monolayer: Low-density nonadherent human bone marrow cells were added in varying numbers to petri dishes with (coincubation) and without (control) normal peripheral blood adherent cells. After the number of adherent cells was calculated, marrow cells were then added to achieve ratios of 0.5:1, 2:1, 3:1, or 5:1 adherent normal cells to nonadherent target cells. Controls contained the same number of nonadherent marrow cells. With low numbers of nonadherent normal cells (higher adherent to nonadherent ratios), two to four identical cultures were established to later retrieve adequate nonadherent cells. Cells were then allowed to coincubate, usually for 4 hours but sometimes for 15 hours. We then extracted nonadherent cells by rinsing the petri dish several times with the supernatant using a Pasteur pipette and washing the dish once with 2 ml α-MEM. The cells were then centrifuged and resuspended to a final volume of 0.5 or 1 ml in α-MEM. Cell recoveries at the end of the 4-hour incubation were equivalent to the number of nonadherent cells, suggesting that target cells were not lost by adherence and that adherent cells did not lose their adherence during coincubation. Target cells were also 100% viable as assessed by trypan blue and contained 2% or less latex-positive cells. Nonadherent target cells incubated in the same way were pooled and cultured. Identical volumes were cultured from coincubation and control experiments and were equivalent to a volume that should contain 1×10^5 cells, if one assumes that the cell counts did not change during the 4-hour culture periods. This procedure eliminated any error in a repeated cell count and also allowed comparisons of 15-hour incubations in which cell counts varied between coincubation and control experiments.

To exclude any entrapment of CFU-C in the monolayers, we included the following controls: The monolayers were overlaid with 0.3% agar α-MEM and HPCM and scored for colony formation 7-14 days later. To eliminate the possibility that PGE_2 secretion prevented the detection of CFU-C, we removed monolayers with PBS-EDTA lidocaine solution and cultured the monolayers in an upper agar layer at 1×10^5 cells with or without 10^{-6} *M* indomethacin and with HPCM in the underlayer. Exposure of nonadherent marrow to PBS-EDTA lidocaine was not associated with loss of GM-CFC, eliminating a possible toxic effect. The GM-CFC entrapment was reexpressed as the number of colonies per 1×10^5 previously coincubated marrow cells. For instance, if four colonies were recovered from 1×10^5 adherent cells in a coincubation experiment performed at a ratio of 0.5:1 adherent to nonadherent cells, these colonies would be derived from 2×10^5 nonadherent cells. The number from 1×10^5 nonadherent cells would equal two. For the determination of the number of CFU-C not retrieved from control cultures, the dishes were treated identically, the suspensions were pelleted, media were removed, and the minute number of cells were resuspended with agar α-MEM and cultured on three plates. The total number of colonies on all three plates would be derived from the total nonadherent cells in the cultures.

Entrapped CFU-C derived from these calculations were identical to those derived from a colony incidence when monolayers from coincubations or the bottom of the dishes from control incubations were overlaid with agar α-MEM and HPCM. With the overlayer experimental approach, the colonies would be derived from all the incubated nonadherent cells, approximately 1.2×10^6 in a 0.5:1 coincubation or 3×10^5 in a 2:1 coincubation. A general schema of this experimental approach is given in text-figure 1.

TEXT-FIGURE 1.—Adherent cell inhibition of GM-CFC and leukemia cluster growth: Experimental design.

Culture procedure.—The culture procedure was described previously (*10*). The marrow preparations were cultured in equal volumes of double-strength α-MEM with 30% FCS and 0.6% agar (Bacto-agar; Difco Laboratories, Detroit, Mich.), giving a final concentration of 0.3% agar with single-strength α-MEM and 15% FCS. For all cultures, 0.1-0.3 ml of HPCM was used as a source of colony-stimulating factor in underlayers of 0.5% agar and α-MEM with 15% FCS. All cultures were plated in triplicate and incubated for 7-14 days in a fully humidified atmosphere of 7% CO_2 and air at 37°C.

Culture scoring.—Cultures were scored on days 7-14 with an Olympus dissecting microscope at × 25-40. They were analyzed for total number of colonies (aggregates of ≥40 cells) per plate. The final incidence was the mean colony incidence from each plate. Individual colonies were picked up with a Unopette pipette (Becton, Dickinson & Co., Rutherford, N.J.) and fixed on egg-albumin-smeared microscopic slides that were etched in small squares on the back by a diamond pencil (1 colony/square) (*11*). After the colonies were dried, they were stained for 2 hours with Luxol fast blue MBS (Hartman-Leddon Co., Philadelphia, Pa.). Subsequently, the slides were rinsed and kept in distilled water for another 2 hours and then counterstained with Harris' hematoxylin for 2 minutes. The staining solution consisted of 0.1 g Luxol fast blue in 100 ml of 70% alcohol saturated with urea. The percentage of each morphologic type of colony presented is based on examination of 50 colonies or more per observation.

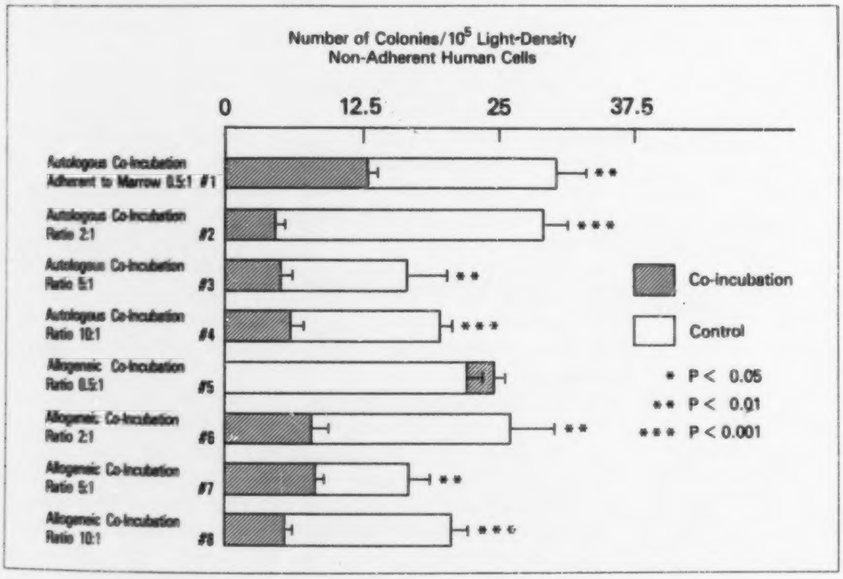
Statistics.—Differences between the results of experiments were examined with the use of a two-sample Student's *t*-test. All comparisons were two-sided.

RESULTS

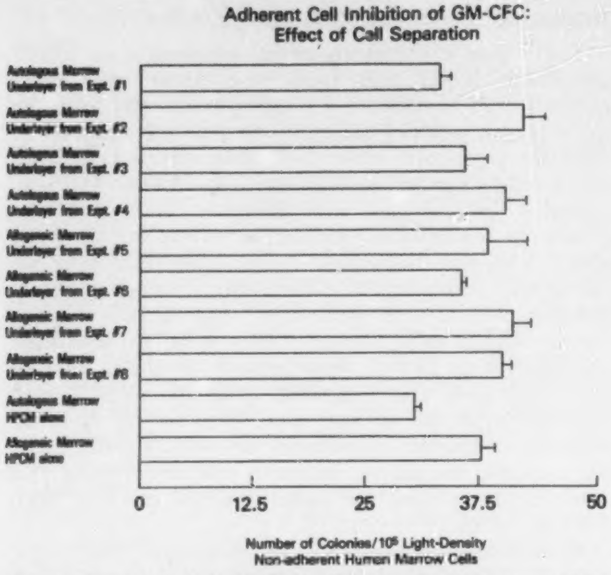
Text-figure 2 shows an initial experiment in which peripheral blood cells from one donor were coincubated with nonadherent bone marrow cells from the same person (autologous mix) and a second experiment with the peripheral blood and bone marow cells from unrelated donors (allogeneic mix). Suppression of CFU-C occurred in cultures with adherent cells and was present at lower ratios of adherent cells to marrow cells (0.5:1) with the autologous combination than with the allogeneic combination. When suppression occurred, colonies fell to 12.5 or less/10^5 light-density nonadherent human cells. However, these adherent cells were stimulatory to CFU-C when placed on the bottom of the petri dish and separated from the nonadherent marrow target by an agar layer (text-fig. 3). Here all cultures contained 25 colonies or more. Furthermore, all cultures containing adherent cell underlayers had more colonies than the target marrow cultured with HPCM alone.

Conditioned media were also harvested after coincubation. Incubating fresh nonadherent marrow cells for 4-15 hours in liquid culture with these conditioned media at 10-100% (vol/vol) did not lower subsequent CFU-C recovery (data not shown).

Text-figure 4 shows the cumulative data from these experiments and the next group of experiments performed. CFU-C were suppressed in 5 of 7 of these experiments at ratios of 2:1 or greater adherent cells to nonadherent normal marrow cells. However, at higher marrow cell numbers (lower ratios of adherent cells to marrow cells), the results were variable, with stimulation occurring in three of seven experiments. Because inhibition occurred more regularly at lower marrow cell numbers, later experiments were performed at

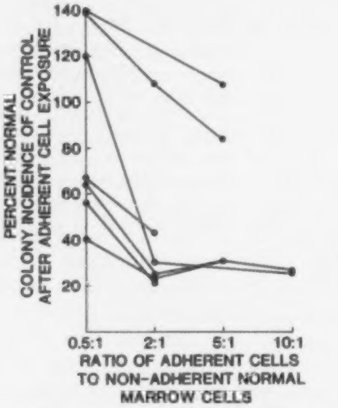


TEXT-FIGURE 2.—Adherent cell inhibition of CFU-C: Autologous combinations also suppress. Peripheral blood adherent cell layers were prepared from 1 donor. Nonadherent bone marrow from the same donor (autologous) or from an unrelated donor (allogeneic) was cultured at various concentrations for 4 hr with or without an adherent layer before removal and culture in agar for assay of CFU-C. Results are means ± SEM of triplicate cultures.



TEXT-FIGURE 3.—Peripheral blood adherent cells when separated by agar from nonadherent marrow target do not suppress. The same adherent layers (6×10^5 cells) used for coincubation expts 1-8 in text-fig. 1 were overlaid with 0.5% agar after coincubation, and the cells recovered from the equivalent control cultures were cultured at a volume equivalent to 1×10^5 nucleated cells in an upper layer. Comparison with control cultures in text-fig. 1 shows the lack of inhibition. Nonadherent bone marrow cells cultured directly into agar are also shown for comparison. Results are means ± SEM of triplicate cultures.

ratios of 3:1 and 5:1. We have now performed 20 experiments and have seen suppression in allogeneic mixes in 16. Suppression was absent when the percentage of adherent cells was low (≤10%), and the monolayers so formed were nowhere near confluence.



TEXT-FIGURE 4.—Adherent cell modulation of CFU-C growth: Effect of the ratio of adherent to nonadherent marrow cells. Nonadherent marrow cells were cultured in liquid with or without adherent cell underlayers created by adherence at two cell concentrations. CFU-C incidence of nonadherent marrow without prior culture is also given for comparison of CFU-C survival in liquid culture. Results are the means ± SEM of triplicate cultures.

Approximately 50% of these experiments were performed with the inclusion of 10^{-6} *M* indomethacin in liquid, solid, and both phases, and no differences in the results were seen.

Monolayers harvested from these coincubations and plated in agar with or without 10^{-6} *M* indomethacin did not contain more than 2 CFU-C/10^5 previously coincubated nonadherent bone marrow cells. This number was usually equivalent to the number of adherent CFU-C recovered from control petri dishes incubated for 4 hours with nonadherent marrow. Because sparse monolayers were sometimes associated with no inhibition, monolayers were also prepared for the next set of experiments at concentrations of 4×10^6/ml and 2×10^6/ml.

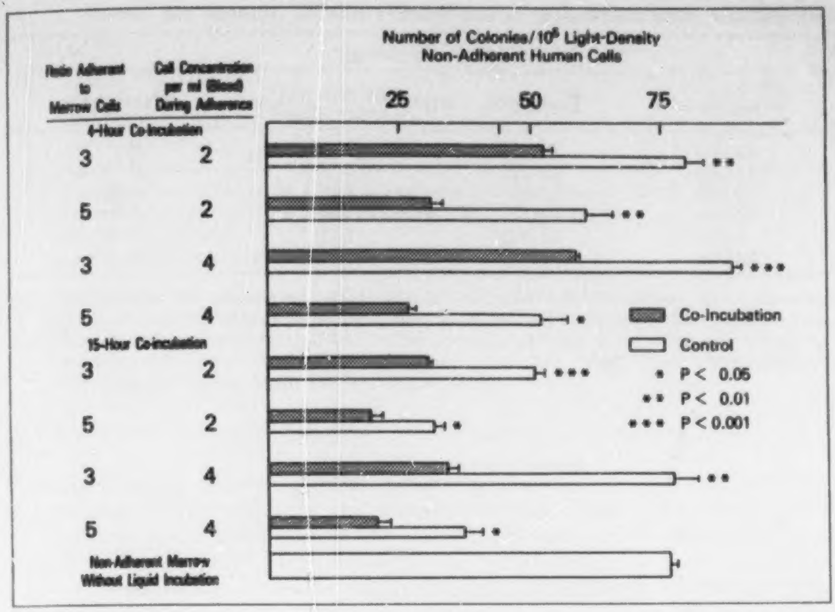
Inhibition was demonstrated with 15-hour coincubation as well as with 4-hour coincubation, but, as shown in text figure 5, was not enhanced by prolonged coincubation. Inhibition was also seen when cultures were scored at day 14, suggesting that these results were not related to a growth delay (text-fig. 6). However, morphologic examination of the colonies showed that suppression was specific. Neutrophilic colonies were markedly suppressed, whereas eosinophilic colonies were not, and there were too few data to delineate the relative sensitivity of granulocyte-macrophage or macrophage CFU-C (table 1). Differences were not associated with increased cluster growth in coincubation experiments. Both colonies and clusters were inhibited equally.

These results seemed reminiscent of the in vivo situation. In blood, neutrophilic colonies do not circulate much and circulating CFU-C are predominantly eosinophilic (*11*).

Therefore, we reasoned that if what we had shown was physiologically relevant, adherent cells from marrow should not suppress GM-CFC, inasmuch as these CFU-C are abundant in marrow. Also these experiments would serve as a control to show that adherent monolayers from other sources in general did not suppress CFU-C growth.

Text-figure 7 is representative of four other experiments. When coincubated on monolayers from marrow, CFU-C scored at day 7 (neutrophilic) showed significantly enhanced recovery. Moreover, the differences at day 14, when eosinophilic colonies were more pronounced, were not significant; if anything, they favored a slight increase in the controls (table 2). Adherent monolayers from marrow contained 0-2 CFU-C/10^5 nucleated cells. However, after coincubation CFU-C were recovered from these monolayers in greater numbers—a finding not observed with peripheral blood adherent cells.

To delineate further the nature of the peripheral blood adherent cells responsible for this inhibition and to be sure that the inhibition did not require T-lymphocyte interaction, we also did experiments with T-cell-depleted nonadherent marrow targets and adherent layers formed after T-cell removal (table 3). Addition of increasing numbers of T-cells induced extra

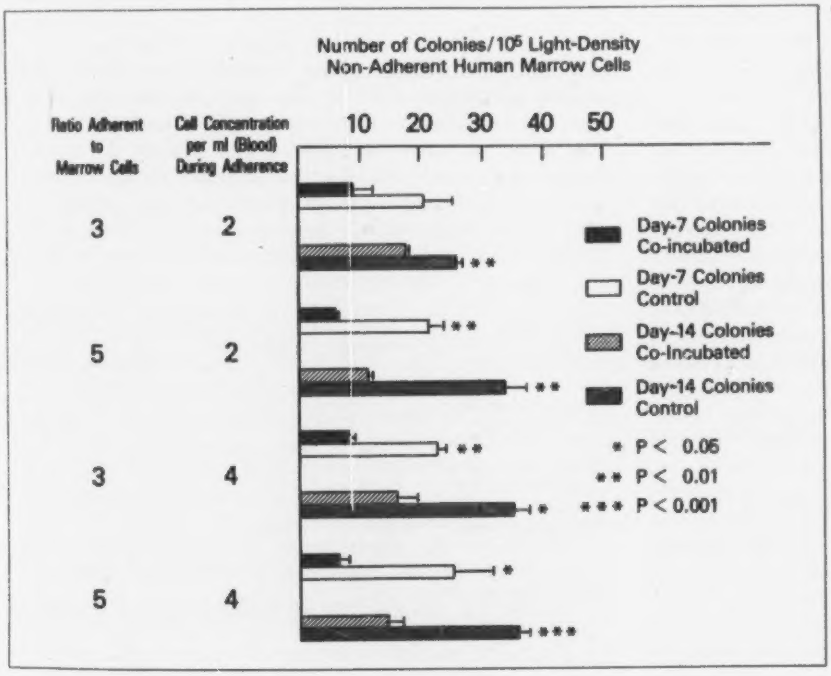


TEXT-FIGURE 5.—Adherent cell modulation of CFU-C growth: Effect of more prolonged cell contact. In addition, the effect of preparation of denser monolayers was studied by the incubation during adherence of 4×10^6 cells/ml. Results are the means ± SEM of triplicate cultures.

colony-forming cells from the controls, which was probably secondary to lymphoid CSA release synergizing with HPCM. The doses of HPCM used in all experiments were at plateau dose-responsive levels. Suppression was still seen, regardless of whether adherent monolayers were formed before or after T-cell removal. Adding T-cells again did not increase the suppression.

DISCUSSION

These experiments examine for the first time the short-term effects of cell-cell interactions between adherent cells and CFU-C progenitor cells. The results appear compatible with what happens in vivo, where predominantly eosinophilic progenitor cells circulate (*11*, *12*). The relative absence of GM-CFC in the



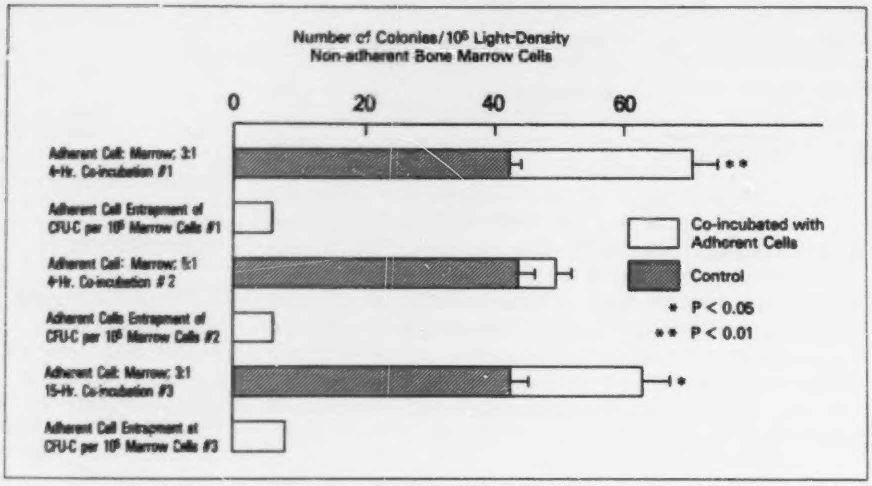
TEXT-FIGURE 6.—Adherent cell modulation of day-7 and day-14 CFU-C growth. As in text-fig. 5, inhibition was compared between monolayers prepared from the incubation of 2 and 4×10^6 cells/ml. Results are the means ± SEM of triplicate cultures.

TABLE 1.—*Suppression of granulocytic colonies from nonadherent human marrow cells by adherent cell contact*

Expt No. and procedure	Day of analysis	Colony morphology[a]			
		Granulocyte	Eosinophil	Granulocyte–macrophage	Macrophage
1. Coincubation	9	35 (45)	35 (45)	8 (10)	0
Control		112 (78)	31 (22)	0	0
2. Coincubation	14	3 (19)	11 (67)	2 (12)	1 (2)
Control		19 (48)	11 (28)	7 (19)	2 (5)
3. Coincubation	10	5 (20)	15 (57)	2 (8)	4 (15)
Control		26 (49)	20 (38)	7 (13)	0

[a] Results are absolute No. of colonies/standard volume of culture (%). *See* "Materials and Methods" for details. All colonies from the three plates of any individual experiment were harvested. The minimum No. analyzed was 51 colonies in the coincubation of expt 2, the total No. and percentage of each individual colony were calculated, and the absolute No. of any individual colony type was divided by 3 to express the No. on an individual culture dish.

TEXT-FIGURE 7.—Marrow adherent cell modulation of CFU-C growth. Nonadherent marrow cells were cultured in liquids of various concentrations with or without adherent underlayers derived from marrow. In contrast to peripheral blood adherent underlayers, marrow underlayers improved day-7 CFU-C survival. Also, significant numbers of CFU-C were detected within the adherent underlayers.



circulation may be related to inhibition of their growth by circulating adherent cells.

For inhibition to occur, there must be favorable ratios of adherent cells to marrow cells. One of the many possible explanations is that too high a number of marrow cells may block interactions between adherent cells and CFU-C. The question arises whether such ratios or circumstances exist in peripheral blood. In vivo cells are mobile, and the chance of interaction would be greatly magnified. Possibly, these interactions occur primarily at the vessel wall, where monocytes may be concentrated by margination. Lastly, a possible competition or blocking of a monocyte receptor for CFU-C by peripheral blood cells may not be as effective as that of cells such as promyelocytes and myelocytes in a nonadherent marrow fraction.

A number of potential technical artifacts to explain these results were eliminated. First, loss of CFU-C was not related to viable entrapment in the monolayer. Monolayers that were removed and cultured did not contain more than 2 CFU-C/10^5 previously coincubated marrow cells. Certainly, this amount was not sufficient to explain the gross differences between results in coincubation and control experiments. This failure to recover CFU-C does not exclude the possibility that CFU-C were entrapped within the monolayers. Some may have been, and failure to recover them may have been due to the fact that they were rendered nonviable. This probable entrapment of CFU-C is suggested by the fact that we can routinely recover CFU-C in considerable numbers from marrow

TABLE 2.—*Day-14 colonies after coincubation on marrow adherent underlayers*

Experimental procedure	Colonies[a]	Colony morphology[b]

adherent layers. Second, this inhibition was not due to monocytes lifting off from the monolayers and being transferred to the solid cultures. If sufficient monocytes were loosened when we retrieved the nonadherent target, suppression could be mediated by PGE_2 secretion during agar culture. This was a possibility that we had to rule out because PGE_2 can preferentially suppress noneosinophilic colonies (*3, 13*). However, after most coincubation experiments we had less than 2% latex-positive cells. Cell recoveries were close to 100%, and the inclusion of indomethacin at 10^{-6} *M* in liquid, solid, or both phases made no difference to the inhibition. Finally, these same monolayers, when overlaid with agar and separated from the target by an underlayer, enhanced CFU-C growth. This observation would suggest that if there was some transference of monocytes, it would have a positive influence on growth.

The information from the above-mentioned experiment and the fact that media harvested from these coincubation experiments did not suppress CFU-C growth argue strongly against a soluble factor mechanism. It would be unusual to generate significant factors within 4 hours that could be detected by tests in agar culture. This failure to detect an inhibitory factor from these media does not totally rule out a short-range, locally concentrated factor.

As a further control to rule out the possibility that poor CFU-C recovery was related to differing numbers of cells in liquid culture in coincubation and control experiments, we prepared adherent cells from a different source, human bone marrow. In this situation, recovery of day-7 CFU-C (neutrophilic) was greater in coincubation experiments, with no significant difference at day 14. Adherent cells from marrow are certainly contaminated with peripheral blood, but the composition of monocytes is lower than that of adherent monolayers prepared from blood (*6, 9*). Monocytes usually comprise 60% or less of the adherent layer. These monocytes may be derived from both blood and marrow. Other cells in these monolayers include metamyelocytes, some juvenile polymorphs, myelocytes, and lymphoid cells. Why monolayers created from marrow are more favorable to GM-CFC proliferation will be investigated. Some have suggested that marrow monocytes or macrophages are a different subset from peripheral blood monocytes or macrophages with consequent different actions on hematopoiesis (*5*). Another proposal is that other cells within the adherent layer modify the action of the monolayer. This proposal could explain the variability in inhibition when higher marrow numbers are used in coincubation experiments with peripheral blood adherent cells.

We chose to use freshly derived adherent cells rather than to create monolayers from tissue culture-derived macrophages. We thought this approach would better mimic the in vivo situation. As with leukemia cluster inhibition demonstrated previously (*7*), normal GM-CFC inhibition appears unlikely to be a cytostatic phenomenon. The mechanism behind the CFU-C loss remains to be elucidated. Whether this is classical cytotoxicity, as shown by macrophages or human monocytes toward tumor cell lines (*14-18*), can be resolved only by an experiment in which we radioactively label purer populations of CFU-C.

It has been postulated that different differentiation tendencies in different organs, (e.g., myelopoiesis in marrow, erythropoiesis in spleen, and lymphopoiesis within the lymph node) are determined by different microenvironments (*19-25*). These inductive microenvironments are thought to be related to different fibroblast populations (*22, 23*). However, different directions of differentiation conceivably could be due to negative or positive controls exerted by other adherent cells within different organs. This adherent population is highly likely to consist predominantly of monocytes or macrophages. These cell populations are known to interact by a cell-to-cell contact mechanism with lymphocytes and, as a consequence, to regulate lymphopoiesis (*26*). Alternatively, any of these phenomena may be simply mechanisms to limit hematopoiesis to the marrow, where it may be finally regulated. At the same time, soluble factors from these cells may enhance hematopoiesis, a long-range regulatory mechanism, which thus would allow tissue invasion by microorganisms to be recognized and translated into increased marrow hematopoiesis.

ABSTRACT—This report presents a detailed analysis of 8,915 cases of malignant lymphomas accumulated since the inception of the Pathology Panel and Repository Centers for Lymphoma Clinical Studies in 1967. Of 8,915 cases 3,105, 34.8%, were classified as Hodgkin's disease (HD) and 5,061 cases, 56.8%, were classified as non-Hodgkin's lymphoma (NL) according to the final diagnosis. In HD, nodular sclerosis was the most common type (1,730/3,105 cases, or 55.7%), followed in order of frequency by mixed cell type (865/3,105, 27.9%), lymphocyte depletion type (224/3,105, 7.2%), and lymphocyte predominance type (94/3,105, 3%). Children showed a higher incidence of the lymphocyte predominance (16/129, 12.4%) and nodular sclerosis (76/129, 58.9%) categories. In cases having the diagnosis and classification of HD provided by the contributors 51.6% (1,523/2,953) were confirmed by final diagnoses. The nodular sclerosis subtype was the most reproducible category of disease, and was confirmed in 83.8% of the cases (912/1,088). The category of HD most difficult to reproduce proved to be the lymphocyte predominance subtype, in which the concurrence by the panel was only 23.3% (41/176). Major disagreements between the contributors and the panel on the diagnosis and subclassification of HD occurred in 16.7% (494/2,953) of the cases. When the diagnoses of the Regional Center, composed of member(s) of the panel serving cooperative groups, and the final diagnoses were compared, the incidence of complete agreement in the classification of HD was appreciably higher (2,747/3,080, 89.2%) than when the diagnoses and classification of HD provided by the contributors were compared with the final diagnoses (1,523/2,953, 51.6%). However, the experts also had difficulties with the lymphocyte predominance category, with an agreement incidence of 73% (79/108). The major disagreement in the classification of HD between the diagnosis of the Regional Center and the final diagnosis was 3.8% (118/3,080). In NL, poorly differentiated lymphocytic lymphoma showing varying degrees of nodularity had the highest incidence (1,284/5,061, 25.4%); diffuse histiocytic lymphoma was next highest (1,248/5,061, 24.7%), followed by diffuse poorly differentiated lymphocytic type (467/5,061, 9.2%). However, lymphoblastic lymphoma became the third or fourth most common form of NL in the years 1977–79 after it was identified and separated from diffuse poorly differentiated lymphocytic lymphoma. We believe that this is related in part to the participation of Children's Cancer Study Group during this time period. The incidence of agreement for NL was less than that for HD. The contributor's diagnosis was verified with regard to both pattern and cytology in 48.6% (1,674/3,441) of NL cases. Nodular poorly differentiated lymphocytic lymphoma and diffuse histiocytic lymphoma, representing 50% (2,532/5,061) of all NL cases, were confirmed most often by the Panel in 80.4% (518/644) and 71.9% (590/821) of the cases, respectively. Diagnoses of the contributors were confirmed in less than 35% of the cases in the following categories: nodular well-differentiated lymphocytic lymphoma, nodular histiocytic lymphoma, diffuse poorly differentiated lymphocytic lymphoma, diffuse mixed-cell lymphoma, lymphocytic lymphoma of the intermediate degree of differentiation, and undifferentiated malignant lymphoma. Major disagreements were higher with regard to NL cases (1,143/4,190, 27.3%) than to HD cases (494/2,953, 16.7%). The agreement of the final diagnosis with the Regional Center diagnosis for nodular poorly differentiated lymphocytic lymphoma was 95%, and for diffuse histiocytic lymphoma, 89%. Major disagreements between the Regional Center's diagnosis and the final diagnosis (435/4,993, 8.7%) were also significantly less than major disagreements between contributor's and final diagnosis. With regard to correct pattern recognition, the contributors were more often correct in the diagnosis of nodular or nodular and diffuse NL (86.3%) than in that of diffuse NL (74.6%). This analysis shows *a*) that difficulties in the diagnosis and classification of malignant lymphomas by the contributors persist, *b*) that the disagreement resulting from this difficulty can be lessened when reviewed by an experienced hematopathologist, and *c*) that it can be further

reduced through a central review process by a panel of experts.—JNCI 1982; 68:43-67.

The Lymphoma Task Force was organized under the auspices of the National Cancer Institute in 1964 to bring together a group of investigators whose primary interest was in malignant lymphomas. The goal was to achieve a multidisciplinary and multi-institutional approach to the management of malignant lymphoma. Difficulties in the classification of malignant lymphomas made it desirable to establish a pathology reference and repository center for lymphoma clinical studies. Clinicians of the cooperative study groups took the initiative to create such a center in 1967 (*1*). In the same year, the Pathology Panel and Repository Center actually started to receive slides from patients entered in protocol studies of the various cooperative study groups. The primary purpose was to provide these groups with confirmation or revision of the original diagnosis by a panel of experts who were recognized as having special expertise in hematopathology. Initially, they were selected to membership of the Pathology Panel on the basis of their scientific and professional achievements without regard to their affiliation with study groups. These pathologists were in charge of Regional Centers serving at least one cooperative study group. In addition, a clinician-hematologist with expertise in the various therapeutic programs was appointed to the panel. Currently, all regional pathology centers are headed by the chairmen of the lymphoma pathology subcommittees of each cooperative study group.

The Chairman and the Executive Secretary of the Panel perform the functions of the Repository Center. They are also the principal and co-principal investigators of the NCI grant that provides financial support for the Pathology Panel and Repository Center for Lymphoma Clinical Studies.

Every protocol case was reviewed independently by the Regional Centers and Repository Center. When diagnoses of the Regional Centers and Repository Center differed, the cases were presented to the annual meeting of the entire panel. The main functions of the panel were: *a*) resolution of diagnostic disagreements between the Repository Center and Regional Centers, and *b*) identification of problems in the diagnosis and classification of malignant lymphomas. The creation of the Pathology Panel and Repository Center for Lymphoma Clinical Studies was the first effort of this kind by pathologists to organize themselves in a categorical discipline of pathology. The dual purpose was: *a*) to offer their skills and expertise to their clinical colleagues to confirm or to revise the diagnosis of record, thus to provide a uniform histopathologic review of all cooperative group lymphoma cases, as well as to allow for more valid comparison of therapeutic response and survival data, and *b*) to form a cohesive group that would be available for advice and counsel in areas pertaining to histologic diagnosis and classification of malignant lymphomas and allied diseases. The organization was unique in that it incorporated a central review process in addition to the review by experts at the regional level.

This report covers the period from 1967, when the Pathology Panel and Repository Center for Lymphoma Clinical Studies was created, through the end of

February 1980. In this report our purpose is to present a detailed analysis of 8,915 cases accumulated since the inception of the panel and to identify areas of difficulty in the diagnosis and classification of malignant lymphomas by pathologists.

MATERIALS AND METHODS

Case entry and review procedure.—When a clinical investigator entered a new patient in the study, the contributing pathologist was asked to forward pretreatment diagnostic material (stained and/or unstained sections and/or paraffin blocks with corresponding pathology report) to the study group operations office. Histologic material obtained by the group office was then forwarded to the member of the Pathology Panel at the Regional Center, assigned to that study group. The panel members, their assignments, and their periods of appointment are shown in table 1. These panel members, representing the Regional Centers, rendered their diagnostic interpretation and recorded both their own and the contributing pathologist's opinion (entry diagnosis) on the same report. The report was then sent to the group office, where it was filed with the on-study card, and to the principal investigator of the study group, who was responsible for the care of the patient. The Repository Center also received the report along with histologic material. Electron microscopy and special histochemical and cytochemical stains were performed at the Repository Center for further study of selected cases where such studies were indicated and feasible. All slides submitted to the Repository Center were reviewed, and a diagnosis was rendered. When there was agreement between the Regional Center and Repository Center, it was recorded. If the opinion of the Repository Center did not agree with the diagnosis of the Regional Center, or the Regional Center did not wish to accept the opinion of the Repository Center, the case was submitted to the entire Pathology Panel at its annual meeting to seek consensus. When the diagnosis of the Regional Center was modified by the Repository Center or by the Panel, a final corrected report was forwarded to the originating cooperative group operations office. The term *final diagnosis* will be used in this paper to refer to either the diagnosis agreed upon by both Regional Center and Repository Center or, when such an agreement could not be reached, the consensus diagnosis of the panel.

Pathology Report Form for Lymphoma Clinical Studies.—The Rye classification (modified Lukes-Butler classification (*2*) and modified Rappaport classification (*3, 4*) were employed. In accordance with changes in concepts and terminology of non-Hodgkin's lymphomas, however, the Pathology Report Form for Lymphoma Clinical Studies was changed four times (text-fig. 1) during this period. The computer codes were incorporated in the last report form. Table 2

TEXT-FIGURE 1 (continued).—Pathology report form for lymphoma clinical studies. c) Report form used from 1977 to August 1978. d) Current report form, used since September 1978.

shows a complete list of code symbols for diagnosis, as used by the Repository Center, Regional Centers, and Study Groups.

Explanation of code symbols.—The code symbols for diagnosis are the same as those used for the current Pathology Report Form for Lymphoma Clinical Studies, and most are self-explanatory. The codes HD and UK are essentially the same; they were used for those cases that were diagnosed as Hodgkin's disease but for which a subclassification was lacking for unknown reasons. The same is true for the codes NL and UO for non-Hodgkin's lymphoma. The codes UN and UC were used for cases of Hodgkin's disease and non-Hodgkin's lymphoma, respectively, that were specifically stated to be unclassifiable. The code UL pertains to cases that were either not diagnosable with certainty as malignant tumors, or when they were diagnosable as such, could not be further classified. Cases received at the Repository Center without diagnosis were assigned the code UW. The code OT refers to cases of miscellaneous categories, which include benign lymphoid proliferation, nonlymphomatous hematopoietic malignancies, carcinoma, sarcoma, malignant histiocytosis, angioimmunoblastic lymphadenopathy, mycosis fungoides, lymphoepithelioid cellular lymphoma, composite lymphoma, malignant tumor (not otherwise specified), and others.

Case material.—Since the creation of the Pathology Panel and Repository Center, a total of 8,915 cases have been reviewed as of February 28, 1980. Detailed analyses of these cases and their discussion are presented below.

ANALYSIS OF DATA

The results of the analyses are shown in tables 3-18.

Case distribution according to histology and study group by Regional Center diagnosis and final diagnosis (table 3).—Of 8,915 cases, 3,080 (34.5%) were classified by Regional Centers as HD, 5,039 (56.5%) as NL, and 796 as miscellaneous categories. Final diagnoses are shown *in parentheses* for comparison. The overall difference between the diagnoses of each study group and the final diagnoses is relatively small. Further comparisons between the two are shown in tables 8 and 9 for HD, and in tables 12 and 13 for NL.

Composition of HD case material: According to the Regional Center diagnoses, HD comprised 20.3% (42/207) for Children's Cancer Study Group (CCSG) to 44.2% (729/1,648) for Southeastern Cooperative Cancer Study Group (SEG) of all cases treated by each group. Intergroup Hodgkin's Disease in Children (IHDC) treated only HD patients. Table 3 shows that IHDC and CCSG, both of which manage pediatric age

TABLE 2.—*Code symbols for diagnosis*

Type of disease:	
HD	Hodgkin's disease, not otherwise specified (NOS)
NL	Non-Hodgkin's lymphoma
OT	Other miscellaneous categories
UL	Unclassifiable
UW	Not available
Hodgkin's disease:	
LP	Lymphocytic predominance
NS	Nodular sclerosis
MC	Mixed cellularity
LD	Lymphocytic depletion
UN	Unclassifiable
UK	Classification not available
Non-Hodgkin's lymphoma:	
WD	Lymphocytic, well differentiated
ID	Lymphocytic, intermediate differentiation
PD	Lymphocytic, poorly differentiated
LL	Lymphocytic, not otherwise specified
LC	Lymphoblastic
MI	Mixed-cell type
HI	Large-cell (histiocytic)
BT	Undifferentiated, Burkitt's type
NB	Undifferentiated, non-Burkitt's type
UD	Undifferentiated, not otherwise specified
OR	Other
UC	Unclassifiable
UO	Classification not available
Pattern of non-Hodgkin's lymphoma:	
N	Nodular
D	Diffuse
V	Indeterminable
Y	Nodular and diffuse
X	Not available

groups, have a high incidence of LP (11.4% and 11.9%, respectively, compared with the national average of 3.5%) and NS (60.2% and 61.9%, respectively, compared with the national average of 55.6%). Conversely, LD is much rarer in children. The relative proportion of LP, NS, MC, and LD is similar in different study groups, although some variations are present for LP and LD.

Composition of NL case material: NL comprised 45% (509/1,132) for Cancer and Leukemia Group B (CALGB) to 71% (147/207) for CCSG according to the Regional Center diagnoses. The ratios for NL to HD are highest for CCSG (3.5:1) and Eastern Cooperative Oncology Group (ECOG) (3:1). Table 3 also shows *a*) the rarity of nodular lymphoma and *b*) the high incidence of LC, BT, NB, and UD (combined total of 122/147, 83%) in the pediatric age group. The ratio of PDN+PDY to MIN+MIY varied from 2:1 Western Cancer Study Group (WSG) to 3.9:1 at the Southwestern Oncology Group (SWOG). These variations imply that the therapeutic results for PDN versus MIN obtained by different study groups cannot be compared since the criteria for diagnosis of PD and MI may be different for different Regional Centers.

Case distribution according to final diagnosis and diagnoses of contributor, Regional Center, and Repository Center (table 4).—According to the final diagnosis, 34.8% (3,105/8,915) of cases were classified as HD, 56.8% (5,061/8,915) as NL, and the remainder as miscellaneous categories. The relative percentage of each histologic subgroup is shown in the table. PD showing varying degrees of nodularity (PDN+PDY) is the most common diagnosis (1,284/5,061, 25.4%); the second in frequency is HID (1,248/5,061, 24.7%). There were 715 cases of miscellaneous categories of which 113 (1.3%) of the cases were considered to be nonneoplastic lesions according to final diagnosis.

Table 4 shows that the differences between the contributor's diagnosis and final diagnosis are much greater than the differences between diagnoses by the Regional Center, Repository Center, and final diagnosis, respectively. Histologic subtypes for which greatest differences were evident are indicated. Further details of the disagreement between the contributor's diagnosis and the final diagnosis are shown in tables 6 and 7 for HD, and in tables 10 and 11 for NL.

Case distribution according to final diagnosis and year (table 5).—This table shows the yearly trend as well as variations for each of the histologic categories. For example, the incidence of PDD decreased as the number of cases of LC (*5*) increased, which demonstrates the fact that most of the LC had been classified as PDD prior to its recognition. LC has become the third or fourth most common type of NL after PDN+PDY, HID, and MIN+MIY in the years 1978-79. The participation of CCSG during this time period is believed to be responsible for the increase of LC cases in addition to the ability to recognize LC as an entity. LC outnumbered PDD in the ratio of 1.7:1 (61:36) in 1978, and by 1.4:1 (49:34) in 1979. In HD, the relative incidence of LD has dropped from 4.9% of all cases submitted (13.5% of all HD) in the year 1969 to 1.4% (4.1% of all HD) in 1979. There are yearly variations for other subgroups of HD as well.

Comparison of contributor's diagnosis with final diagnosis in HD (final/contributor's) (table 6).—Cases diagnosed as HD and UK were combined as HD in tables 6-9. The following observations can be made on table 6.

1) Agreement	1,523/2,953 (51.6%)
2) Major disagreement	
a. Diagnosis changed to NL	249/2,953 (8.4%)
b. Diagnosis changed to OT[21]	127/2,953 (4.3%)
c. Good-risk diagnosis (LP, NS, or MC)[22] was changed to poor-risk diagnosis (LD)	69/2,242 (3%)
d. Poor-risk diagnosis was changed to good-risk diagnosis	49/205 (23.9%)
Total major disagreement	494/2,953 (16.7%)

---

[21] *See* table 6 for details.

[22] Inclusion of MC under good risk diagnosis is based on survival data in recently reported series of HD treatment (*6, 7*).

[a] *See* table 2 for code symbols.
[b] Percentages according to final diagnosis.
[c] Histologic subtypes for which greatest differences in diagnoses were found between the sources of diagnoses.

3) Other findings
   a. Contributors had the greatest difficulty in correctly recognizing LP. Their diagnoses are confirmed in only 23.3% of the cases they submitted as LP.
   b. Most (83.8%) of the contributors' diagnoses of NS proved to be NS.
   c. 28.6% (280/978) of the contributors' diagnoses of MC were changed to NS, whereas only 6.4% (70/1,088) of their NS diagnoses were changed to MC.
   d. It is difficult to distinguish between LD and HI, 16.6% (34/205) of contributors' diagnoses of LD were changed to HI.

Comparison of final diagnosis with contributor's diagnosis of HD (contributor's/final) (table 7).—This table shows:

1) Agreement (excluding 461 cases without contributor's diagnosis)	1,523/2,644 (58.2%)
2) Major disagreement	
a. Contributor's diagnosis was NL	63/2,644 (2.4%)
b. Contributor's diagnosis was among OT	6/2,644 (0.2%)
c. A final good-risk diagnosis (LP, NS, or MC) was considered to be a poor-risk diagnosis (LD) by contributors	49/2,294 (2.1%)
d. A final poor-risk diagnosis	69/191[23] (36.6%)

---

[23] Of the 224 cases with a final diagnosis of LD, the contributor's diagnosis was unavailable in 33 cases.

TABLE 5.—*Case distribution according to final diagnosis and year*[a]

identified only 61.3% (912/1,487) of all NS cases. 18.8% (280/1,487) of NS was classified as MC.

b. 30.4% (58/191[23]) of LD was considered to be MC by contributors.

Comparison of Regional Center's diagnosis with final diagnosis of HD (final/Regional) (table 8).—This table can be summarized as follows:

1) Agreement 2,747/3,080 (89.2%)
2) Major disagreement
  a. Diagnosis changed to NL 42/3,080 (1.4%)
  b. Diagnosis changed to OT 37/3,080 (1.2%)
  c. Good-risk diagnosis (LP, NS, MC) was changed to poor-risk diagnosis (LD) 15/2,703 (0.6%)
  d. Poor-risk diagnosis was changed to good-risk diagnosis 24/229 (10.5%)
    Total major disagreement 118/3,080 (3.8%)
3) Other findings:
  a. LP has the lowest agreement rate (73%).
  b. Disagreement rate is significantly less than for the results shown in table 6.

Comparison of final diagnosis with Regional Center's diagnosis of HD (Regional/final) (table 9).—This table shows:

1) Agreement 2,747/3,105 (88.5%)
2) Major disagreement
  a. Regional Center's diagnosis was NL 35/3,105 (1.1%)

TABLE 7.—*Hodgkin's disease: Comparison of final diagnosis with contributor's diagnosis*[a]

Total	1	10	20	85	1,695	834	209	147	1	1	4	1	12	15	1	7	37	3,080 [100]

[a] For code symbols, *see* table 2.

[b] *Values in parentheses* are No. of cases. *Bold face values* represent agreement for each histologic subtype when compared with final diagnosis.

b. Regional Center's diagnosis was among OT — 17/3,105 (0.5%)

c. A final good-risk diagnosis (LP, NS, or MC) was considered to be a poor-risk diagnosis (LD) by the Regional Center — 24/2,689 (0.9%)

d. A final poor-risk diagnosis was considered to be a good-risk diagnosis by the Regional Center — 15/224 (6.7%)

Total major disagreement — 91/3,105 (2.9%)

3) Others

LP has the lowest agreement rate (60.9%).

Comparison of contributor's diagnosis with final diagnosis of NL (final/contributor's) (table 10).—In the comparison of the diagnoses for NL shown in tables 10-13, four quadrants of each square were utilized to specify different pattern designations as follows: upper left quadrant—nodular, upper right quadrant—nodular and diffuse, lower left quadrant—diffuse, lower right quadrant—pattern not available or indeterminable. In analyses for tables 10-13, a designation of nodular versus nodular and diffuse was considered a disagreement when complete agreement was computed. The findings of table 10 can be summarized as follows:

1) Complete agreement for both cytologic type and pattern (excluding cases without cytologic and/or pattern designation) — 1,674/3,441 (48.6%)

2) Major disagreement

a. Diagnosis changed to HD — 57/4,190 (1.4%)

TABLE 9.—*Hodgkin's disease: Comparison of final diagnosis with Regional Center's diagnosis*

d. Diffuse pattern designation changed to nodular or nodular and diffuse	257/2,196 (11.8%)
e. Good-risk diagnosis (all WD, all ID, PDN, PDY, MIN, and MIY) changed to poor-risk diagnosis (PDD, all LC, MID, all HI, all BT, all NB, and all UD	167/1,469 (11.4%)
f. Poor-risk diagnosis changed to good-risk diagnosis	305/2,435 (12.7%)
Total major disagreement	1,143/4,190 (27.3%)
3) Others	
a. Contributor's WDN changed to PDN or MIN	117/158 (74%)
b. Contributor's PDN confirmed	468/644 (72.7%)
c. Contributor's HID confirmed	590/821 (71.9%)

Comparison of final diagnosis with contributor's diagnosis of NL (contributor's/final) (table 11).—

1) Complete agreement for both cytologic type and pattern, excluding cases without designation of cytology and/or pattern	1,674/4,367 (38.3%)
2) Major disagreement	
a. Contributor's diagnosis was HD	246/5,037 (4.9%)
b. Contributor's diagnosis was among OT	704/5,037 (14.0%)
c. Nodular or nodular and diffuse lymphoma was considered by contributors to be diffuse lymphoma	262/1,920 (13.6%)
d. Diffuse lymphoma was considered by contributors to be nodular and diffuse lymphoma	91/2,525 (3.6%)
e. Good-risk categories (all WD, all ID, PDN, PDY, MIN, and MIY) were considered to be poor-risk categories (PDD, all LC, MID, all HI, all BT, all NB, and all UD) by contributors	325/2,071 (15.7%)
f. Poor-risk categories were considered to be good-risk categories by contributors	162/2,613 (6.2%)
Total major disagreement	1,790/5,037 (35.5%)

Comparison of Regional Center's diagnosis with final diagnosis of NL (final/Regional) (table 12).—

1) Complete agreement for both cytologic type and pattern, excluding cases without designation of cytology and/or pattern	3,612/4,372 (82.6%)
2) Major disagreement	
a. Diagnosis changed to HD	34/4,993 (0.7%)
b. Diagnosis changed to OT	125/4,993 (2.5%)
c. Nodular or nodular and diffuse designation changed to diffuse	44/1,873 (2.3%)
d. Diffuse designation changed to nodular or nodular and diffuse	94/2,563 (3.7%)
e. Good-risk diagnosis (all WD, all ID, PDN, PDY, MIN, and MIY) changed to poor-risk diagnosis (PDD, all LC, MID, all HI, all BT, all NB, and all UD)	58/2,048 (2.8%)
f. Poor-risk diagnosis changed to good-risk diagnosis	80/2,678 (3%)
Total major disagreement	435/4,993 (8.7%)

Comparison of final diagnosis with Regional Center's diagnosis of NL (Regional/final) (table 13).—

1) Complete agreement for both cytologic type and pattern, excluding cases without designation of cytology and/or pattern	3,612/4,367 (82.7%)
2) Major disagreement	
a. Regional Center's diagnosis was HD	41/5,037 (0.8%)
b. Regional Center's diagnosis was among OT	174/5,037 (3.5%)
c. Nodular or nodular and diffuse lymphoma was considered to be diffuse lymphoma by Regional Center	90/1,920 (4.7%)
d. Diffuse lymphoma was considered to be nodular or nodular and diffuse lymphoma by Regional Center	45/2,526 (1.8%)
e. Good-risk categories (all WD, all ID, PDN, PDY, MIN, and MIY) were considered to be poor-risk categories (PDD, all LC, MID, all HI, all BT, all NB, and all UD) by Regional Center	84/2,071 (4.1%)
f. Poor-risk categories were considered to be good-risk categories by Regional Center	47/2,518 (1.9%)
Total major disagreement	481/5,037 (9.5%)

Comparison of contributor's diagnosis with final diagnosis of nodular, or nodular and diffuse NL (final/contributor's) (table 14).—This table shows the degree of confirmation of the pattern designated by contributors for those cases interpreted by them as either nodular or nodular and diffuse NL. "No agreement" means that the final diagnosis was something other than NL; "agree on NL only" means that the final diagnosis was NL, but both pattern and cytologic classification were different from those of the contributors; and "total agreement" means that the final diagnosis was identical to that of the contributors for both pattern and cytology. A correct pattern designa-

tion (total pattern agreement) consists of the sum of the percentages of agreement on pattern only and of total agreement. For the purpose of computing the agreement percentage for the pattern designation of NL in tables 14-17, we considered N versus Y as agreement, whereas D versus N or Y was considered a disagreement. Table 14 shows that:

1) When contributors diagnosed nodular or nodular and diffuse NL, their pattern designation was confirmed in 86.3% of the cases.

[a] Diffuse vs. nodular and diffuse pattern designations were considered disagreement.

high as that obtained when they classified cases as nodular or nodular and diffuse NL (86.3%).

2) An improvement in designation diffuse pattern from 62.3% in 1972 to 80.8% in 1979 was noted.

Comparison of final diagnosis with contributor's diagnosis of diffuse NL (contributor's/final) (table 17).—The definition for each column of figures in this table is same as for table 14. This table shows that:

1) In diffuse NL, the contributor's pattern designation was confirmed in 65.8% of cases.
2) There has been an improvement in:
    a. Correct pattern designation from 41.4% in 1972 to 77% in 1979.
    b. Total agreement from 34.5% in 1972 to 47.9% in 1979.

The percentages of agreement for the subtypes of HD and NL are summarized in tables 18 and 19, respectively.

Agreement in percents for different histologic subtypes of HD when diagnoses of contributors and Regional Center are compared with final diagnosis (table 18).—This table shows that:

1) NS is the most reproducible (61.3% to 94.3% incidence of agreement) and LP is the least reproducible category (23.3% to 84% incidence of agreement).
2) When contributors mistakenly designated as NS cases not confirmed as such by the final diagnosis, these cases were most likely to have been classified as MC, as shown in table 8.
3) There is a significant difference in percent agreements between contributor's versus final diagnosis and Regional Center's versus final diagnosis.

Agreement in percents for different histologic subtypes of NL when diagnoses of contributor and Regional Center are compared with final diagnosis (table 19).—This table shows that:

1) PDN and HID, the two most common subcategories of NL, are the most reproducible with an incidence of agreement ranging from 46.3 to 95% for PDN and from 47.3 to 89% for HID.
2) MID and PDD are the least reproducible among the major categories. The incidence of agreement ranges from 18.9 to 80% for MID and from 31.7 to 80.5% for PDD.

TABLE 18.—*Agreement for different histologic subtypes of Hodgkin's disease when diagnoses of contributor and Regional Center are compared with final diagnosis*[a]

[a] N vs. Y pattern designation was considered agreement for categories WD, PD, MI, and HI.

[b] Based on data from table 10.

[c] Based on data from table 11.

[d] Based on data from table 12.

[e] Based on data from table 13.

[f] For this table, differences in pattern designation were not considered as disagreement in categories ID, LC, BT, NB, and UD since these are almost always diffuse.

[g] There are some questions whether N vs. Y designation represents true disagreement in the PD category. Some of the panel members do not consider the use of Y as a separate subcategory worthy of a special designation. However, in the analysis pertaining to "all NL" (last line of table) we have chosen to consider as disagreement every diagnostic designation that does not represent a complete agreement.

3) There is a significant difference in percent agreement between contributor's versus final diagnosis and Regional Center's versus final diagnosis.

Reproducibility of classification in HD and NL (table 20).—This table summarizes some of the findings mentioned above. The analysis confirms that *a*) difficulties persist in the diagnosis and classification of malignant lymphomas by contributors, *b*) the resulting disagreements in diagnosis can be lessened by a review by an experienced hematopathologist (Regional Center) and that *c*) disagreements can be further reduced by a central review process done by a panel of experts. It also reveals that reproducibility of diagnosis and classification for HD is better overall than for NL.

DISCUSSION

The importance of accurate diagnosis and classification of malignant neoplasms of the immune system is universally accepted. It is particularly important for the evaluation of clinical trials in which the histologic diagnosis plays an important role in the selection of an appropriate mode of therapy (*8*). Review of the histologic material by a pathologist is, in most instances, an initial step in the entry of patients into any of the protocols for clinical trial studies. This review process ensures not only that a correct diagnosis has been established but also that a patient population within a histologic subtype is homogeneous for evaluation and comparison of clinical results. It also identifies problems in diagnosis and classification that are not appreciated by pathologists who have limited exposure to such case material. It is, therefore, not surprising that the papers by Jones et al. (*9*) and Russell (*10*), in particular, emphasize the need of having the histopathologic material of all cases entered in major protocol studies reviewed by someone other than the original pathologist. It has also been recognized that accuracy of diagnosis and consistency in classification can be achieved better by a panel of experts than by individual pathologists with different degrees of expertise (*11*).

The creation of the Pathology Panel and Repository Center in 1967 (*1*) afforded the opportunity for two independent and separate review processes by a panel of expert hematopathologists in the clinical study of malignant lymphomas. This study, based on 8,915 cases accumulated since its inception, shows disagree-

TABLE 20.—*Reproducibility of classification in HD and NL*

Extent of agreement	Diagnosis	Final/contributor, %	Contributor/final, %	Final/Regional Center, %	Regional Center/final, %
Complete agreement	HD NL	48.6 51.6	38.3 58.2	82.6 89.2	82.7 88.5
Major disagreement	HD NL	27.3 16.7	35.5 7	8.7 3.8	9.5 2.9

ment on diagnosis and classification between contributors and experts and, to a lesser extent, among experts themselves, thus confirming the need for such a review process, as expressed by other investigators.

Of the total 8,915 cases, 3,105 (34.8%) were classified as HD and 5,061 (56.8%) as NL according to the final diagnosis (table 4).

In the HD group, NS was the most common type (1,730/3,105, 55.7%), although the incidence was not as high as reported in some series at individual institutions (*6, 12*). The relatively high number of unclassified cases (92/3,105, 6.2%) is, in part, attributable to the submission of histologic sections of either extranodal tissue or spleen only, without initial diagnostic biopsy. The most likely explanation for the different proportion of HD, which ranged from 20.3% to 44.2% of all cases in different study groups, was the level of activity of active protocols in the groups during the period under study (table 3).

The variation, however, in the incidence of each subtype of HD should be a true reflection of the study groups' patient populations since the same histologic criteria were utilized for all study group cases (table 3). It is of particular interest that pediatric patients with HD have higher incidences of LP and NS than do patients of all age groups with HD; this finding is based on cases submitted by IHDC and CCSG from trials limited to children. Reproducibility of classifying HD can be considered in different ways and levels of expertise. If one looks at the contributor's classification of HD and compares it with the final diagnosis (table 6), the agreement rate was 51.6% (1,523/2,953). NS was the most reproducible subtype and was confirmed in 83.8% of cases (912/1,088). Conversely, contributors designated only 61.3% (912/1,487) of all NS correctly, because they classified a considerable percentage of NS as MC. This misclassification may be due to their unawareness of the Ann Arbor criteria, (*13*) according to which all cases of HD should be classified as NS even if histologic features for NS can be identified only in focal areas. The diagnostically least reproducible category of HD proved to be LP, which was confirmed only in 23.3% (41/176). Most of the cases classified by the contributors as LP were changed to NS or MC. When one examines all cases of HD confirmed by the panel, the overall accuracy of the contributors' classification remains similar (1,523/2,644, 58.2%), but the LD category shows the lowest percentage of agreement because, in a significant number of cases, LD was considered by the contributors to be MC.

Of great importance are the cases listed under "major disagreement" in the above analysis of data. Such major disagreements occurred between contributors and the panel in 16.7% of the HD cases (494/2,953). Some misinterpretation or disagreement on the classification of malignant lymphoma is unavoidable even among experts. This fact is shown in tables 8 and 9, which compare the classification of the Regional Centers with that of the final diagnosis for HD. Although the incidence of complete agreement among panel members if appreciably higher, experts also have difficulties in the same areas. For example, the disagreement rate between the Regional Center diagnosis and final diagnosis with respect to LP and LD was also higher than that for NS and MC. NS was again the most reproducible classification, with an agreement rate of more than 93%. The agreements for different histologic subtypes of HD, when diagnoses of contributors and Regional Centers are compared with the final diagnosis, are summarized in table 18, expressed in percentages.

The NL comprised from 45% (509/1,132) for CALGB to 71% (147/207) for CCSG (table 3). Among the NL, PDN+PDY had the highest incidence (1,284/5,061, 25.4%); HID was next (1,248/5,061, 24.7%), followed by PDD (467/5,061, 9.2%). However, if lymphoblastic lymphoma (LC) is excluded from PDD, as is done in table 5, LC becomes the third or fourth most common form of NL in the years 1977–1979. It is not certain how much of the difference in the ratio of PDN+PDY to MIN+MIY among the different Regional Centers reflects a true difference in their incidence or a difference in the histologic criteria used. It is certain, however, that the different Regional Centers employ different criteria for classifying PDN or PDY versus MIN or MIY since, for example, the ratio for the ECOG cases changed from 3.9:1 to 8.5:1 with the change of the head of the Regional Center. This variation in the ratio of PDN+PDY versus MIN+MIY still exists even when the ratio is calculated according to the final diagnosis. This is due to the difficulty of establishing generally acceptable objective criteria for the distinction between these two subtypes short of actual counting of large and small cells. Hence, the Repository Center is reluctant to disagree with Regional Centers on this particular problem of classification. This may explain the different therapeutic results reported by different investigators when one compares the PDN+PDY and MIN+MIY groups (*14–16*).

The CCSG data shown in table 3 reaffirm the extreme rarity of nodular lymphomas in the pediatric age group. As expected, LC, BT, NB and UD accounted for the majority of the pediatric NL (122/147, 83%). Since their distinction is based on morphologic differences which are quite subtle even in histologic sections of the best possible technical quality, the high incidence of LC, BT, NB and UD makes it especially challenging to classify children's NL with the greatest possible precision.

With regard to the percentages of complete agreement, the results for NL are less favorable than those for HD. The contributor's diagnosis was verified as to both pattern and cytology in only 48.6% (1,674/3,441) of cases (table 10). In WDN, ID, PDD, MID, HIN and UD, the diagnoses of contributors were confirmed in less than 35% of the cases (table 19). In most instances, WDN was changed to PDN. When the comparison of reproducibility in NL was based on final diagnosis, the incidence of correct identification by the contributors of both pattern and cytology was even lower (1,674/

4,367, 38.3%) (tables 10 and 19). Major disagreements occurred with a higher percentage in NL (1,143/4,190), 27.3%) than in HD (494/2,953, 16.7%). Included among the major disagreements were NL versus HD, pattern disagreements, and good risk diagnosis versus poor risk diagnosis.

On the other hand, PDN and HID were confirmed most often by the panel (518/644, 80.4%, for PDN and 590/821, 71.9%, for HID) (table 19). This is significant inasmuch as PDN and HID combined represent 50% (2,532/5,061) of all NL. Among the experts, the agreement rates for PDN and HID were 95% and 89%, respectively. With the exception of WDN, ID, MID and UD, all categories showed agreement in more than 70% of the cases (tables 12 and 19). Major disagreement was also significantly less than when contributors' and Regional Center's diagnoses were compared. Nevertheless, major disagreements constituted 8.7% (table 12) to 9.5% (table 13), depending on how the diagnoses were compared. As far as correct pattern designation is concerned, contributors' diagnoses were more often confirmed in nodular or nodular and diffuse NL (86.3% agreement) than in diffuse NL (74.6% agreement). Tables 14 and 15 also indicate that the contributors fail to designate nodularity in a significant proportion of nodular NL (39.7%), although, when they classified NL as nodular, they usually were confirmed (86.3%). Tables 14-17, in which reproducibility of opinions on NL pattern and/or cytology is analyzed, show trends toward gradual improvement in the designation of pattern and/or cytologic subcategories. Whether this trend for improvement is due to an educational effort by the Pathology Panel and Repository Center for Lymphoma Clinical Studies is difficult to prove.

In summary, this comprehensive analysis shows that difficulties persist in the diagnosis and classification of malignant lymphomas by contributors. It confirms the findings of other studies based on some of the ECOG (*17*) and SWOG (*9*) material included in this study and on other case material (*18*). The resulting disagreements can be lessened appreciably by the review of a panel of experts. Our analysis reveals, in addition, that the same difficulties of diagnosis and classification exist, although to a lesser extent, among the experts themselves. The disagreement can be reduced further by a central review process aimed at a consensus for each case on which disagreement exists (table 20). This has been achieved by a process of reconciling differences in diagnosis and classification either by correspondence or during the annual meeting of all panel members.

Maximizing Differences in the Concanavalin A-Induced Blastogenic Responses of Lymphocytes From Breast Cancer Patients and Controls by the Use of α-Methyl-D-mannoside [1,2,3]

John A. Distasio, [4] **David A. Cheresh,** [4] **Russell J. Schilder,** [4] **Charles L. Vogel,** [5]
Michael A. Silverman, [5,6] *and* **Diana M. Lopez** [4,7]

ABSTRACT—In an attempt to magnify differences in the immune responses of potentially immunosuppressed cancer patients and normal controls, an assessment was made on the effects of the competitive inhibitor α-methyl-D-mannoside on the concanavalin A (Con A)-induced blastogenic responses of lymphocytes from each of these populations. Lymphocytes from breast cancer patients with metastatic disease were significantly deficient in their capability to undergo blast transformation regardless of whether the monosaccharide inhibitor was added to the assay cultures. In contrast, lymphocytes from breast cancer patients who did not display metastatic disease were capable of normal blastogenic responses to Con A. The addition of α-methyl-D-mannoside to lymphocyte cultures caused a significantly greater inhibition of the blastogenic responses of these patients' cells as compared to cells of normal controls. Thus the monosaccharide seems to serve as a useful reagent for optimizing differences between lymphocyte blastogenic responses of normal donors and those of immunodepressed donors. The results suggest that lymphocytes from breast cancer patients without clinically evident metastases possess some modification of their cell membrane. One possibility discussed was that the number or distribution of receptors for Con A on the membrane of lymphocytes of these patients is deficient.—JNCI 1982; 68:69–74.

Evaluation of the immune status of cancer patients has been the subject of many studies (*1–6*). When assaying for cytotoxic responses, blastogenic transformation, delayed-type hypersensitivity reactions, and lymphokine production, some investigators have demonstrated reduced immunocompetence in these patients. In these studies, the cancer patient populations were usually heterogeneous, consisting of patients with advanced disease as well as those with no evidence of metastases. It has been much more difficult to show that cancer patients with early-stage disease are immunosuppressed.

Most investigations of immunocompetence have been performed with the use of optimal assay conditions in an attempt to maximize differences between normal donors and immunosuppressed patients. Fitzgerald (*7*) has demonstrated that by titrating the PHA dose used in a blastogenic assay, it was possible to maximize the difference in response between lymphoid cells from normal donors and those from an immunosuppressed patient with ataxia telangiectasia. In a more recent study, Bernhard et al. (*8*) reported on the effects of varying mitogen concentration and incubation time on the blastogenic responses of lymphocytes from normal donors and cancer patients. Significant differences between the two populations could be maximized when the blastogenic assay was performed with suboptimal concentrations of PHA-M and suboptimal incubation times. For Con A, maximal differences were obtained with optimal concentrations of mitogen and suboptimal incubation times. These investigators (*8*) were able to conclude that modification of assay conditions was useful in distinguishing between the blastogenic responses of normal donors and potentially immunodepressed donors.

Several other studies have been reported demonstrating that assays of immunocompetence performed under suboptimal conditions can be used to detect differences in the immunocompetence of normal individuals and cancer patients. West et al. (*9*) demonstrated that when the rosette assay between T-lymphocytes and sheep red blood cells was performed at elevated temperatures (high-affinity rosette assay), the proportion of RFC of normal adults differed significantly from that of patients with cancer. Specifically, when the assay was done at 20°C, 80% of the cancer

[7] We thank Dr. Marc Saltzman and Dr. Julio Garcia (Miami) for providing some of the blood samples to perform these studies; Ms. Ileana Zapatero and Ms. Anna Salazar (University of Miami) who worked on this project as undergraduate research assistants; Ms. Dawn East, Ms. Chris Kahl, Ms. Darlene Padgett, and Ms. Margaret Szaro (University of Miami Hospitals and Clinics) for identifying suitable patients for our study, confirming clinical characteristics of patients, and blood drawing; Ms. Susan Hilsenbeck (Comprehensive Cancer Center for the State of Florida) for performing the statistical analyses; and Dr. Robert Duncan (University of Miami School of Medicine) for his helpful comments.

patients had normal levels of RFC, whereas when it was done at 29°C, 41 of 50 patients had significantly depressed proportions of RFC. Using this same assay, Quan and Burtin (*10*) obtained similar results. Moroz and co-workers (*11*) showed that cancer patients' peripheral blood mononuclear cells incubated in the presence of autologous serum had a reduction in RFC by as much as 20% compared to the RFC found among cells incubated in the presence of FCS. Ferritin bound to the surfaces of the cells was shown to be responsible for this reduction. When the same mononuclear cells were preincubated in FCS to remove ferritin, the patients' lymphocytes exhibited increased [^{3}H]thymidine incorporation after stimulation with mitomycin C-treated allogeneic lymphocytes. No increase was observed with lymphocytes from normal donors after cells were preincubated in FCS.

These studies support the concept that some modification of the cell membrane may exist on lymphocytes from cancer patients. The effects of this putative membrane alteration, however, could be observed only by use of suboptimal assay conditions to magnify these differences. Early events in lymphocyte activation appear to involve binding of lectin (e.g., Con A) followed by passive receptor movement resulting in cross-linking of receptor-lectin complexes (*12-14*). Titration of mitogens in blastogenic assays could be useful in the establishment of a concentration that would accentuate modifications in lectin binding. The results of the study by Bernhard et al. (*8*) as presented above may demonstrate this phenomenon. Receptor cross-linking has been shown to be highly dependent on lectin valence (*14-16*). To investigate changes in the capacity of receptor cross-linking that may ultimately affect activation of lymphocytes, one may find it useful to incorporate in the blastogenic assay mixture an agent that has the ability to alter mitogen valence. To explore this possibility, we examined the effects of the monosaccharide α-methyl-D-mannoside on Con A-induced blastogenesis. This sugar acts as a competitive inhibitor for Con A and thus limits the available number of lectin molecules for binding to membrane receptors. More importantly, the sugar binds to one or more of the four available sites on the Con A molecule (*17*) and effectively alters its valence. For our studies, we examined the effects of incorporating α-methyl-D-mannoside in lymphocyte cultures stimulated with Con A. We used a well-defined human breast cancer system in an attempt to avoid such variables as age of donors, effects of cytotoxic drug treatment, and effects of radiation. Our results confirm that suboptimal assay conditions as described by Bernhard et al. (*8*) magnify differences in the Con A-induced blastogenic responses of normal donors and breast cancer patients with metastatic disease, but not in those of patients without clinical evidence of metastases. The addition of α-methyl-D-mannoside to the assay, however, can accentuate differences in the blastogenic responses of lymphocytes from patients without clinical evidence of metastases and from normal controls.

MATERIALS AND METHODS

Patient population.—Before entry into this study, 33 women with breast cancer underwent the following staging procedures: complete medical history, physical examination, and blood and platelet counts; liver function tests; plasma carcinoembryonic antigen assay; chest X-ray; liver and bone radionuclide scans; and confirmatory bone X-rays of bone scan-positive areas. The patients were divided into two subpopulations. The first group consisted of patients with a recent mastectomy for stage II or III breast cancer and positive axillary nodes but no clinical evidence of distant disease. The second group consisted of patients with documented local, regional, or distant metastatic disease. This group was further subdivided into patients with no prior systemic therapy for cancer or none within the preceding year and patients who were treated with cytotoxic chemotherapy 1-6 months previously. Excluded from the study were patients who had received radiation therapy and patients with a history of diabetes mellitus, alcoholism, or any other chronic condition. It took approximately 1½ years to obtain enough patients to perform these studies. The group of women with no clinical evidence of distant metastatic disease consisted of 12 patients with a mean age of 53.3 years (range, 31-75 yr). The group with metastatic disease and no prior systemic therapy for at least 1 year consisted of 13 patients with a mean age of 57.5 years (range, 45-72 yr). The group with metastatic disease and prior cytotoxic chemotherapy 1-6 months before sampling consisted of 8 patients with a mean age of 62.0 years (range, 37-78 yr). For those patients without clinical evidence of metastatic disease, blood was obtained within 2 months of mastectomy. For those patients with metastatic disease, blood was obtained just before systemic therapy. Twenty-eight women with a mean age of 47.0 years (range, 25-73 yr) served as controls. These controls were selected from volunteers in the community who did not have an affiliation with the hospital community or prior history of cancer, who were free of disease, and who were not taking any drugs at that time. Information concerning each patient's stage of disease was withheld from those individuals performing the blastogenic assays until completion of the study.

Isolation of mononuclear cells.—Blood was obtained by venipuncture with the use of syringes containing sufficient heparin (The Upjohn Co., Kalamazoo, Mich.) to yield a final concentration of 100 U/ml of blood. Blood was diluted with an equal volume of sterile saline. Mononuclear cells were isolated by discontinuous density gradient centrifugation (*18*) with the use of LSM (Litton Bionetics Inc., Kensington, Md.). Diluted blood (20 ml) was layered over 15 ml of LSM. The gradients were spun at 400×g for 40 minutes at 19°C. Mononuclear cells were recovered from the interface and washed three times with RPMI-1640 growth medium (GIBCO, Grand Island, N.Y.) supplemented with 10% FCS, 100 U penicillin/ml, and 50 μg streptomycin/ml (Associated Biomedic Systems, Inc., Buffalo, N.Y.). Washed cells were pelleted by centrifugation for 10 minutes at 10°C.

Blastogenesis assay.—Cultures were set up in six replicates with the use of #3040 microtiter plates (Falcon Plastics, Los Angeles, Calif.). To each well was added 0.01 ml of Con A (Calbiochem-Behring Corp., Los Angeles) to yield a final concentration of 5 μg/ml and 0.01 ml of a solution of α-methyl-D-mannoside (GIBCO) to yield a final concentration of 0.875–56.0 mg/ml. To those cultures containing PHA-P (isolated from *Phaseolus vulgaris;* Difco Laboratories, Detroit, Mich.), 0.01 ml was added to yield a final concentration of 6.25 μg/ml. The monosaccharide solutions were sterilized by passage through a Swinnex assembly filter (Millipore Corp., Bedford, Mass.) containing a membrane with a pore size of 0.22 μm. Control cultures contained growth medium instead of mitogen, sugar, or both. Plates were sequentially incubated at room temperature for 15 minutes and at 37°C for 15 minutes. Then 0.18 ml of culture medium containing 1×10^5 mononuclear cells was added to each well. Cultures were incubated for 72 hours in a 5% CO_2, humidified atmosphere. Eighteen hours before being harvested, cultures were pulsed with 0.01 ml of [^{3}H]thymidine solution (50 μCi/ml). Harvesting was facilitated by a Skatron cell harvester (Flow Laboratories, Inc., Rockville, Md.). Cells were collected on #78-105-05 glass fiber filter paper (Flow Laboratories, Inc.) and lysed with water. Filter paper disks containing [^{3}H]DNA were placed in polyethylene vials with 5 ml of a scintillation cocktail of toluene containing 5 g 2,5-diphenyloxazole/liter and 0.2 g 2-(5-phenyloxazoly)-benzene/liter (Yorktown, Inc., Hackensack, N.J.). Vials were enumerated in a Tricarb scintillation counter (model 3330; Packard Instrument Co., La Grange, Ill.).

Only lymphocytes from patients with metastatic disease (untreated for >1 yr) were used in the studies to determine the concentrations of Con A and α-methyl-D-mannoside that would optimize differences between the blastogenic responses of lymphocytes from patients and normal controls. These patients were chosen, since most likely they would be immunodeficient. For each of these experiments, 5 patients and 5 normal controls were used.

Data are presented as the cpm of experimental cultures with Con A minus the cpm of control cultures without Con A. When experimental cultures contained sugar, so did the control cultures at the same concentration. The control cultures never had more than 1,000 cpm. Results were analyzed by computer with the use of the square root transformation of the data in a two-way analysis of variance. Data were considered significantly different at a value of $P<0.05$.

RESULTS

Con A blastogenic responses of lymphocytes from normal human donors and breast cancer patients.—The Con A blastogenic responses of lymphocytes from normal human donors and breast cancer patients with metastatic disease are compared in text-figure 1. The optimal responses for both groups were obtained at 5 μg Con A/ml. This same concentration of Con A resulted in maximal differences between the two populations of lymphocytes. All subsequent experiments were performed with 5 μg Con A/ml. A two-way analysis of variance with the square root-transformed data indicated that the blastogenic responses of the lymphocytes from normal donors and cancer patients were significantly different at concentrations of Con A ranging from 1.5 to 12 μg/ml.

Con A blastogenic responses of lymphocytes from normal human donors and breast cancer patients in the presence of α-methyl-D-mannoside.—The results of the con A-induced blastogenesis of lymphocytes from normal human donors and breast cancer patients with metastatic disease in the presence of α-methyl-D-mannoside are presented in text-figure 2. The blastogenic responses of lymphocytes from both groups were inhibited by the monosaccharide in a dose-dependent manner. The blastogenic responses of lymphocytes from the breast cancer patients, however, were more inhibited than were those of lymphocytes from normal donors at each of the concentrations of α-methyl-D-mannoside tested. Maximal discrimination between the two populations of lymphocytes was obtained at 3.5 mg/ml of the sugar.

Specificity of inhibition of the blastogenic response by α-methyl-D-mannoside.—The specificity of inhibition by α-methyl-D-mannoside of the blastogenic responses of lymphocytes from normal human donors and breast cancer patients with metastatic disease was examined. As much as 14 mg monosaccharide/ml did

TEXT-FIGURE 3.—Effects of α-methyl-D-mannoside on the blastogenic responses of lymphocytes from normal donors and various groups of breast cancer patients. A) The individual blastogenic response when Con A was added to the culture and α-methyl-D-mannoside was omitted. B) The individual blastogenic response when Con A and α-methyl-D-mannoside were added to the culture. Con A was used at 5.0 μg/ml and α-methyl-D-mannoside at 3.5 mg/ml. For other experimental details, *see* "Materials and Methods." The abbreviations used were: non met., patients with no clinical evidence of metastases; met., patients with metastatic disease and untreated for at least 1 yr; met. treated, patients having metastatic disease and receiving cytotoxic chemotherapy within 1-6 mo of being tested.

not inhibit PHA-P-induced blastogenesis of lymphocytes from normal donors or from breast cancer patients (table 1), whereas it effectively inhibited Con A-induced blastogenesis. At higher concentrations of α-methyl-D-mannoside, inhibition did not seem to be specific, since PHA-P and Con A-induced blastogenesis were inhibited.

Inhibition of Con A-induced blastogenesis of breast cancer patients' lymphocytes by α-methyl-D-mannoside.—The Con A-induced blastogenic responses of lymphocytes from normal human donors and various breast cancer patients were determined in a replicate series of experiments with or without α-methyl-D-mannoside (text-fig. 3, table 2). The monosaccharide caused a greater inhibition in the blastogenic responses of lymphocytes from each of the patient groups as compared to lymphocytes from normal donors. Using the square root-transformed data in a two-way analysis of variance, we found a significant difference between the responses of normal lymphocytes and metastatic breast cancer patients' lymphocytes with or without the addition of sugar. This observation was true for patients with metastatic breast cancer who were not on any therapeutic regimen for more than 1 year and for those who were treated between 1 and 6 months before the experiments. In contrast, no significant difference was observed between the Con A-induced blastogenic responses of lymphocytes from normal donors and breast cancer patients without detectable metastases unless 3.5 mg α-methyl-D-mannoside/ml was added to the assay mixture.

DISCUSSION

Various assays have been used to assess the immunocompetence of cancer patients (*1–6*). These studies have demonstrated that cancer patients with metastatic disease usually have suppressed immune responses. Partly due to the inherent variability of the immune responses of humans (*19*), it has been more difficult, however, to demonstrate that patients with earlier stages of disease have impaired immunocompetence. In most studies the assays have been performed under optimal conditions to measure immune responsiveness. More recently, investigators have attempted to vary assay conditions to maximize differences between normal donors and cancer patients (*8–11*). In most of these studies the cancer population consisted of groups of patients who were not homogeneous with regard to the type of cancer they had or the stage of the disease. Using suboptimal incubation times and mitogen concentrations, Bernhard et al. (*8*) were able to maximize differences between the blastogenic responses of lymphocytes from controls and cancer patients hospitalized for primary cancer surgery. No statistical difference was obtained when the assays were performed under optimal conditions. The authors were unable, however, to conclude that the patients' lymphocytes were deficient in their blastogenic responses, since the difference in mean age between the normal donors and cancer patients was 24 years. Catalona et al. (*20*) showed that increasing age correlates with decreasing lymphocyte blastogenic response. Bernhard et al. (*8*) concluded that suboptimal assay conditions were useful in magnifying differences in the blastogenic responses of normal and immunodepressed donors.

Using optimal concentrations of Con A and suboptimal incubation times as established by Bernhard et al. (*8*), we were able to demonstrate that the lymphocytes from breast cancer patients with metastatic disease had significantly reduced blastogenic responses as compared to those found with lymphocytes from normal donors. Breast cancer patients without clinical evidence of metastases did not display such an immunodepression. Using the competitive inhibitor α-methyl-D-mannoside and suboptimal incubation times (*8*), we were able to demonstrate a statistically significant difference between the Con A-induced blastogenic responses of lymphocytes from normal human donors and breast cancers without clinical evidence of metastatic disease. Our results are not likely due to differences in age between the population groups, since the mean age of the cancer patients was 53 years and the mean age of the normal donors was 47 years. Thus the use of the competitive inhibitor α-methyl-D-mannoside in Con A-induced blastogenic assays serves as a sensitive method of magnifying differences in lymphocyte responses of normal donors and those of cancer patients who are potentially immunosuppressed.

We have several hypotheses to explain our observation that α-methyl-D-mannoside causes a greater inhibition of Con A-induced blastogenesis of breast cancer patients' lymphocytes than that of lymphocytes of normal donors. One explanation is that the receptor(s) for Con A are modified on the surfaces of lymphocytes from breast cancer patients. This modification may be a change in the average number of Con A receptors per cell, a change in the average affinity of the receptors, or a change in the number of cells bearing Con A receptors. Since lymphocytes from patients without clinical evidence of metastatic disease do not display decreased blastogenic responses when α-methyl-D-mannoside is omitted from the assay mixture, it is difficult to envisage that lymphocytes from these patients have a reduced number of receptors per cell or number of cells bearing receptors. In addition, less than 15% of mitogen receptors must be bound to mitogen to trigger blastogenesis (*21*). Thus it seems that a large change in the number of receptors per cell would have to exist for a significant reduction in the blastogenic response to occur. Moreover, in preliminary experiments with ^{125}I-labeled Con A, we have demonstrated that the average number of mitogen receptors and the average affinity for lectin are the same on lymphocytes from normal donors and breast cancer patients with metastatic disease.

Alternatively, Con A receptors may be redistributed on the membranes of lymphocytes from the breast cancer patient. While this redistribution has been documented for transformed cells (*22*) and for lymphoid tumors (*23*), it has not been demonstrated for any nonlymphoid cancers. Such a change could be the result of a serum factor binding to the membrane, altering membrane fluidity, and/or preventing cross-linking of ligand-receptor complexes, which might ultimately lead to an inhibition of the triggering mechanism of blastogenesis (*24, 25*). Dunlap et al. (*26*) showed that depression of Con A-induced blastogenesis occurs in cats bearing feline leukemia virus-induced lymphomas and correlated this depression to a decreased capability for Con A receptors to cap. This group of investigators (*27*) has also shown that the p15 protein of feline leukemia virus can similarly inhibit Con A receptor capping on normal human lymphocytes. We are presently examining properties of lymphoid membranes and serum factors from breast cancer patients to explain the decreased Con A-induced blastogenic responses of their lymphocytes in the presence of α-methyl-D-mannoside.

Value of Plasma α-1-Acid Glycoprotein Assay in the Detection of Human Colorectal Cancer: Comparison with Carcinoembryonic Antigen[1,2]

Clement Y-T. Chu, *M.D.,*[3] **Lilian T-Y, Lai,** *M.S.,*[3] *and* **Hari P. Pokala,** *M.D.*[3,4]

ABSTRACT—Plasma specimens assessed for carcinoembryonic antigen (CEA) in the clinical laboratory for the detection of colorectal cancer were simultaneously assayed in our laboratory for α-1-acid glycoprotein (α_1AG), by means of a solid-phase enzyme-linked immunosorbent assay we developed. In 28 patients with colorectal cancer of Dukes A, B, and C classes, elevated levels of α_1AG were seen in 12 and of CEA in 8. In 44 patients with distant metastasis (Dukes D lesions), elevated plasma levels of α_1AG were seen in 29 and of CEA in 34. No statistical differences in the detection rate were found among these markers in these 2 groups of patients. In 33 cases of nonneoplastic disease involving the large bowel, elevated plasma levels of α_1AG were seen in 6, and elevated CEA levels were seen in 7. There was no statistical difference of false positive rates among these two markers. Elevated plasma levels of either CEA or α_1AG were found in 57 cases of colorectal cancer. This preliminary study suggests that the sensitivity of the plasma α_1AG assay is similar to that of the CEA assay in the detection of colorectal cancer. The combination of these two assays increases the detection rate of colorectal cancer significantly.—JNCI 1982; 68:75–79.

α_1AG is a low molecular weight (approximately 40,000) plasma glycoprotein containing 45% carbohydrate in the moiety (*1*). It has been isolated from the plasma in pure form (*2-4*). The structure of its carbohydrate portion and amino acid sequence have been elucidated (*5, 6*). The function of this protein in pathophysiological states is not yet completely known, but recent studies have suggested that it may participate in the modulation of the immunologic response (*7, 8*).

Several studies of changes in plasma levels of α_1AG have been reported (*9-11*). Recently, attention has gradually shifted to the elevation of plasma α_1AG in neoplastic diseases (*12-16*). A preliminary study on the plasma levels of α_1AG in colorectal cancer has been reported by our group previously in abstract form (*17*). In the present study we evaluate the use of plasma α_1AG assay in the detection of colorectal cancer in symptomatic patients and compare its value with that of CEA.

MATERIALS AND METHODS

Aliquots of plasma specimens sent by physicians for CEA assays were obtained from the Clinical Chemistry Department of the Harper-Grace Hospital and were assayed for α_1AG. The clinical records were reviewed without knowledge of results of α_1AG assay. The diagnosis of colorectal cancer in all cases was established histologically. All patients in whom cancer was excluded had complete clinical studies including thorough physical examination, roentgenological study, radioisotope scanning, and in some instances, endoscopic procedures. In those patients in whom cancer was excluded, the major diagnosis was taken as the "diagnosis." There were 72 cases of colorectal cancer studied, including 28 cases with Dukes A, B, and C lesions. Blood samples of these patients were obtained before resection. Another 44 patients, designated as the Dukes D group, had cancer that extended beyond the bowel wall and invaded the contiguous organs or had distant metastases. Blood samples of these 44 patients were taken at least 1 month after the exploratory operations, or after cessation of chemotherapy for more than 1 month and radiation for 3 months. Among the specimens studied, 33 were ultimately proven to be obtained from patients with nonneoplastic diseases involving the large bowel.

A solid-phase enzyme-linked immunosorbent assay developed in this laboratory (*18*) was used to assay plasma α_1AG. In measuring plasma α_1AG levels of 62 normal healthy individuals (aged 18–61), with the exclusion of females who were on oral contraceptives or estrogen compounds, a value of 0.67 ± 0.20 mg/ml (means±SD) was obtained. Since α_1AG values were distributed in the Gaussian fashion (text-fig. 1), the normal range of plasma α_1AG for the healthy population was estimated as 0.27–1.07 mg/ml (mean±2SD). Plasma α_1AG level exceeding 1.07 mg/ml was considered as elevated. This assay has an intra-assay coefficient of variation under 6% and interassay coefficient of variation under 8%.

The CEA assay was performed by the Clinical

ABBREVIATIONS USED: α_1AG = α-1-acid glycoprotein; CEA = carcinoembryonic antigen.

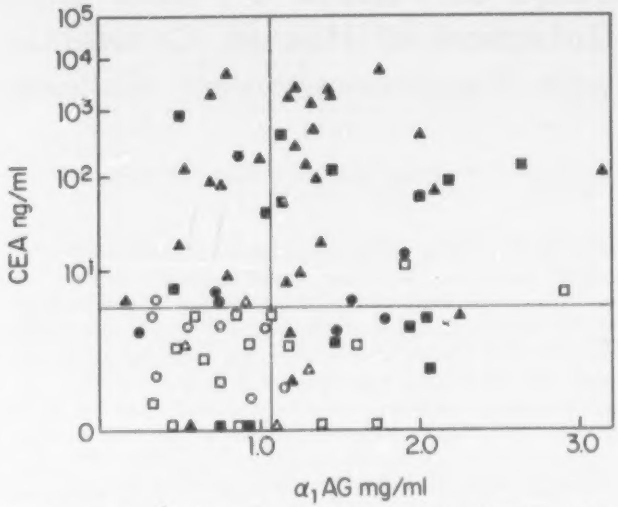
TEXT-FIGURE 1.—Distribution of plasma α_1AG values in healthy subjects.



TEXT-FIGURE 2.—Plasma levels of α_1AG and CEA in 8 patients with benign colon polyps, ○, and in 72 patients with colon cancer at different patologic stages. — Dukes classification: A, △; B, □; C, ●. Liver metastasis, ▲; distal metastasis without liver metastasis, ■.

Chemistry Department of the Harper-Grace Hospital using the CEA kits® (Hoffmann-La Roche Inc., Nutley, N.J.) and the assay procedure suggested by the manufacturer (Hansen's Z-gel assay). The upper normal limit was set at 5 ng/ml since 95% of the healthy individuals of the general population have plasma CEA below this level (*19*), and this cut-off point was considered to be appropriate by many investigators (*20-24*).

Analysis of variance and multiple comparison tests were performed with the use of a Hewlett-Packard HP97 calculator and programmed tapes, the rest of the statistical tests were done by standard statistical methods.

RESULTS

The distribution of elevated plasma α_1AG and CEA values in colorectal cancer patients is shown in text-figure 2. Among the 72 patients, elevated plasma levels of both α_1AG and CEA were seen in 26, elevated plasma levels of α_1AG alone in 15, and of CEA alone in 16. There were no statistical differences between the detection rates in α_1AG (41/72) and CEA (42/72). In 16 cases plasma levels of neither α_1AG or CEA were elevated.

The frequency of elevated plasma levels of α_1AG or CEA in colorectal cancer patients with different pathologic stages are shown in table 1. In the potentially curable Dukes A, B, and C lesions, elevated plasma levels of α_1AG alone were seen in 8 of 28 cases and CEA alone in 4 of 28. In patients with Dukes D lesion, elevated plasma levels of α_1AG alone were seen in 7 of 44 cases and CEA alone in 12 of 44 cases. There was no statistically significant difference among the positive rates of α_1AG and CEA in the potentially curable lesions ($P>0.317$) or in Dukes D lesion ($P>0.317$), analyzed by the McNemar test. Mean values of α_1AG and CEA in different pathologic stages are shown in table 2. Analysis of variance revealed that there was no statistically significant difference among mean values of α_1AG in the different pathologic stages. However, the difference became apparent when the mean value of α_1AG from normal control group was added ($F=12.40$, significant at the $P<0.01$ level). Multiple comparison tests revealed that mean plasma values of patients with Dukes B, C, and D lesions were significantly different from that of a normal healthy control group (table 3).

Correlations of plasma levels of α_1AG and CEA are

[c] Without liver metastasis.

shown in table 4. There was no correlation of plasma levels of α_1AG and CEA in either of the Dukes A, B, C, or D groups, regardless of the presence or absence of liver metastasis in group D.

Among 44 patients with Dukes D lesions, 29 had liver metastasis detected by radioisotope scanning and 15 had no liver metastasis. Plasma α_1AG levels among these 2 subgroups were not statistically different, plasma CEA levels however, were significantly different (table 5).

Frequency of false-positive tests of α_1AG and CEA in nonneoplastic colorectal diseases are shown in table 6. Plasma specimens of 33 symptomatic patients in whom colorectal cancer could not be completely ruled our clinically, were assayed for CEA, and the final diagnosis was nonneoplastic colorectal disease. Among these 33 cases elevated plasma levels of CEA alone were found in 5 and of α_1AG in 4 (table 6). The difference was not statistically significant.

The accuracy of the plasma α_1AG and CEA assays to discriminate between colorectal cancer and nonneoplastic colorectal diseases was statistically evaluated by the chi-square test with Yate's correction for small member samples. We obtained almost identical results with the α_1AG and the CEA assays (tables 7, 8). The discrimination of cancer and nonneoplastic diseases in both assays all reach highly significant levels ($P<0.001$).

When plasma α_1AG assay is performed in addition to CEA assay, the sensitivity of detecting colorectal cancer increases significantly without an increase in the number of misclassifications (table 9).

DISCUSSION

Early studies on the changes of α_1AG level in the plasma in various pathologic conditions stressed the changes seen in acute inflammation and severe surgical trauma. Hence, α_1AG was classified as one of the "acute phase proteins." The potential of using α_1AG in cancer diagnosis was apparently overlooked. In the evaluation of the diagnostic potential of plasma α_1AG assay in cancer, we chose colorectal cancer as the model because colorectal cancer has been the subject of intensive research in the tumor marker studies. We also elected to assay CEA concomitantly for comparison, since the CEA assay had been used extensively in the detection of colorectal cancer. The results suggest that plasma α_1AG assay has a sensitivity similar to that of CEA in the detection of colorectal cancer (table 1). This is true regardless of whether the cancer is an operable Dukes A, B, or C lesion, or an inoperable Dukes D lesion. Mean plasma α_1AG levels increase gradually with the progression of the pathologic stages (table 2). Although simultaneously elevated plasma levels of α_1AG and CEA are frequently seen among patients, α_1AG appears to be a marker independent of CEA (table 4). The actual plasma levels of CEA in Dukes D lesions with liver metastasis were higher than in those without hepatic metastasis, even though the percentage of patients who had elevated levels of CEA did not change (table 5). However, hepatic metastasis does not cause an augmented elevation of plasma α_1AG level in colorectal cancer patients in spite of the fact that α_1AG is synthesized by the liver.

To evaluate a test in detecting colorectal cancer from symptomatic patients, false-positive tests that occur in some nonneoplastic colorectal diseases must be taken into account. In this series, 33 patients who presented with rectal bleeding, constipation, roentgenographic polypoid lesions and stenosis mimicking colorectal cancer, were ultimately proven to be suffering from

nonneoplastic diseases. In this group false-positive tests for CEA were seen in 7 of 33 patients (21%), and α_1AG in 6 of 33 (18%). With the true-positive and false-positive tests in mind, results were analyzed by the chi-square test. It was found that the abilities of these 2 assays in discriminating colorectal cancers and nonneoplastic diseases were very high, $P<0.001$ for both (tables 7 and 8). These results suggest that both α_1AG and CEA assay can be used effectively to detect colorectal cancer in symptomatic patients.

On the basis of observations of multiple tumor markers produced by tumor cells, simultaneous assays of several markers to achieve a greater sensitivity in tumor detection have been recently proposed (*25-27*). Whether a combination of two or more markers brings an improvement in the sensitivity and specificity of cancer detection requires careful study. In this study, we have shown that if both α_1AG and CEA assays are performed, the detection rate of colorectal cancer increases from 58 to 79% ($P<0.01$). Although the specificity will drop from 79 to 67%, the difference is not significant ($P>0.10$). The overall result of this combination is that the sensitivity in cancer detection increases significantly and yet the percentage of misclassified cases does not increase significantly (table 9).

Since there are no correlations of plasma α_1AG and CEA levels in any of the pathologic stages (table 4), plasma levels of α_1AG and CEA represent different parameters. Because of this, the combination of these two assays is not redundant.

In recent years, the major applications of tumor marker assays have been in monitoring the response of tumor to chemotherapy and in detecting early recurrences after tumor resection (*28-31*). Since the combinations of plasma α_1AG and CEA assay increase the detection rate of localized, Dukes A, B, and C, colorectal cancers from 29 to 57% ($P<0.046$), it seems logical to use this combination in the detection of recurrence after tumor resection. Our recent studies also suggested that changes of plasma α_1AG levels correlated well with responses to chemotherapy in cancers of the head and neck (*32*) as well as in metastatic cancer of the stomach (Chu CY-T, Rashid S, Lai LT-Y: Unpublished observation). The study of using serial plasma α_1AG measurements to monitor the response of colorectal cancer to chemotherapy seems warranted.

Various Isozyme Gene Expression Patterns Among Human Colorectal Adenocarcinoma Cell Lines and Tissues[1,2,3]

Lynne P. Rutzky[4] *and* **Michael J. Siciliano**[5]

ABSTRACT—Seven tissue-specific isozymes—lactate dehydrogenases A and B (LDHA and LDHB), esterases B2 and A4 (ESB2 and ESA4), creatine kinase B (CKB), and red blood cell and tissue forms of adenosine deaminases (ADA)—were examined in the human adenocarcinoma cell line LS174T and its subclones grown under a wide variety of conditions. Strong expressions of ESB2, ESA4, and CKB were stable in all material studied, as was a greater expression of LDHA than of LDHB. ADA isozyme expression varied with culture conditions. Identical expression of the five stable isozymes was observed in six surgical specimens of normal bowel mucosa, while cell lines derived from normal mucosa varied in the expression of these isozymes. An additional 23 colorectal cell lines, derived from primary or metastatic adenocarcinomas in different stages of invasiveness and differentiation from 18 individuals, were verified as to their origin by genetic signature analysis and similarly studied for isozyme expression. These lines had different, yet stable, gene expression patterns similar to differences observed among six adenocarcinoma surgical specimens. These differences could not be related to the number of passages that the cell lines were in culture nor to the stages of the tumors at the time that the cell lines were initiated or surgical samples tested. Gene expression patterns in adenocarcinomas differed, these differences might have been due to the origin of colorectal adenocarcinomas from different cell types within a heterogeneous mucosa, and tne colorectal cell lines studied represented appropriate models for colon cancer.—JNCI 1982; 68:81-90.

Until recently, the difficulties encountered in studying viable colon cancer tissue such as heterogeneous populations, microbial contamination, necrosis, and insufficient viable cells impeded an understanding of its biology and possible treatment. Cultured cell lines ameliorate many of the problems. Although human colon tumors have been refractory to in vitro propagation, several cell lines (*1-7*) are now available for investigation of the unique biological, biochemical, and immunological properties of the disease.

To be relevant and useful, cell lines must be continuously evaluated for genetic integrity and maintenance of stable neoplastic properties. During the last 5 years, one set of cell lines, LS180 and its trypsinized variant LS174T (*6*), have been monitored for growth properties, carcinoembryonic antigen production (*8-10*), and karyology (*11*).

In the present study, we examined 24 colorectal tumor cell lines derived from 18 individuals for 13 electrophoretically polymorphic loci to establish their genetic signatures (*12-14*) and to verify their independent genetic origin and freedom from HeLa contamination (*15*). LS174T (our reference line) and its subclones were studied for the expression of seven tissue-specific isozymes after growth under a variety of conditions. Five isozymes were found to be stably expressed in the line and all its subclones. The expression of these isozyme loci was then compared to other colorectal tumor lines, cell lines derived from normal bowel mucosa, and six paired normal bowel and colon adenocarcinoma surgical specimens. Results indicate that the patterns of gene expression in LS174T and certain other tumor lines reflect those of normal bowel mucosa. Other colorectal tumor cell lines may have different, yet stable, patterns, which were also observed among the six adenocarcinoma surgical specimens. These differences could not be related to the number of passages the cell lines were cultured nor to the differentiated or disseminated state of the tumors the time that cell lines were initiated or surgical samples were studied. The possibility that different expressional patterns are due to the origin of colon adenocarcinomas from one of several cell types within a heterogeneous mucosa is discussed.

MATERIALS AND METHODS

Cell cultures.—Cell lines LS180 and LS174T were established in our laboratory from a moderately well-differentiated primary human colon adenocarcinoma

tumor (*6, 11*). LS174T cells were routinely subcultured with 0.1% trypsin (GIBCO, Grand Island, N.Y.) diluted in 0.02% Versene; LS180 cultures were mechanically subcultured with a rubber policeman and have never been exposed to exogenous proteolytic enzymes. Monolayer cultures were grown in EMEM with Hanks' salts supplemented with nonessential amino acids (Eagle's), 10% heat-inactivated (56°C, 30 min) FBS (Sterile Systems, Logan, Utah), 2 m*M* L-glutamine, 50 μg streptomycin/ml and 50 U penicillin/ml. The cells were incubated at 37°C in an atmosphere of 95% air, 5% CO_2, and 95% humidity. The cell lines were mycoplasma-free as determined by transmission and scanning electron microscopy, by the absence of cytoplasmic fluorescence with Hoechst Bisbenzimid H 33258 dye (American Hoechst Corp., North Somerville, N.J.) (*16*), and by negligible arginine deiminase activity (*17*).

Normal bowel cells, NB(LS174T), NB-V, NB-M, and NB(LS123), were derived from the large bowel mucosa dissected at sites distinct from the tumor masses in 4 adult patients. NB(LS174T), LS180, and LS174T were derived from the same patient. Trypsin dissociation of the normal bowel tissue yielded a mixed population of cells, which became predominantly fibroblastic with prolonged subculture. The cells were cultured in the medium noted above. An average of 17 serial subcultivations was achieved with NB(LS174T) cultures before they senesced (*18*). The cells were predominately diploid throughout subcultivation (*11*). Two cell cultures Hs00764Int and Hs0677Int, derived from human fetal intestinal tissue were obtained from Dr. W. Nelson-Rees (University of California Naval Biosciences Laboratory, Berkeley, Calif.). The Hs cell cultures were produced with support from the Viral Oncology Program, National Cancer Institute, under the auspices of the Office of Naval Research and the Regents of the University of California.

Twelve independently derived colorectal carcinoma cell lines of primary or metastatic origin were provided by Col. A. Leibovitz, formerly of the Scott and White Clinic, Temple, Tex. The cultures were sent to us as lysed homogenates, and all are designated with SW-prefixes: 48, 403, 742, 802, 837, 948, 1116, 1222, 1345, 1398, 1417, and 1463. HT-29, an established human colon tumor cell line, was provided by Dr. Jørgen Fogh (Sloan-Kettering Institute for Cancer Research, Rye, N.Y.). HeLa was supplied by Dr. J. Clarkson, The University of Texas System Cancer Center, Science Park, Smithville, Tex. Cell lines LS123 and NB(LS123) were established in our laboratory in 1974 from 1 patient's human colon adenocarcinoma and normal large bowel mucosa, respectively. Genetic signature analysis revealed that LS123 and NB(LS123) were identical and distinct from the LS180 and LS174T cell lines (*11*). Two human colon tumor cell cultures, COLO 205 (*5*) and COLO 399, and frozen cell pellets of COLO 206, COLO 320, COLO 321, COLO 394, COLO 396, and COLO 463 were supplied by Dr. G. E. Moore, Denver General Hospital, Denver, Colo.

Cloning.—LS174T cells at TC 10, 11, 13.6, and 80.4 were cloned by two methods. The cells were placed into 60-mm petri dishes (Falcon Plastics, Oxnard, Calif.) treated with poly-D-lysine (*19*). Glass cloning rings were used to isolate single cells. Clones 10-1, 10-2, 10-3, 10-4, 9-1, 9-2, and 8-1 were subcultured and frozen in liquid nitrogen. Clones 3-5 and 6-6 were isolated by similar procedures by Dr. I. Tribbe (Abbott Laboratories, North Chicago, Ill.). Some clones were isolated by seeding cells on sterile precleaned, broken glass cover slips. After overnight incubation, glass fragments with one adherent cell were transferred to MicroTest II wells (Falcon Plastics), monitored for growth, and subcultured . Subclones of clones 3-5, 6-6, 10-1, and 10-4 were isolated in either 0.3% soft Noble agar (Difco Laboratories, Detroit, Mich.) or agarose (SeaKem; FMC Corp., Marine Colloids Division, Springfield, N.J.), according to the procedures of Macpherson and Montagnier (*20*).

Tumorigenicity studies.—Ten million cells of LS174T, LS180, or of clones 3-5, 6-6, 10-2, 10-3, or 10-4 were inoculated sc in 4 nude mice (*nu/nu* Swiss mice) by the methods of Giovanella and Stehlin (*21*). Tumors were measured weekly for at least 120 days. Animals were killed, tumors were removed, and portions of the tissue were dissected and processed for histologic examination, tissue culture, and isozyme analysis. In every instance, the tumor cells outgrew the mouse stromal cells in culture, and the tumor cell types could be identified by morphology and isozymes. The tumors were either trypsin or mechanically dissociated and cultured in either EMEM or L-15 medium containing 10% heat-inactivated FBS. After four to eight serial passages, the cell cultures were examined for isozyme profiles.

Surgical specimens.—Six pairs of autochthonous human bowel tumor and normal bowel mucosa specimens and one unpaired normal bowel mucosa specimen were examined for gene expression. The tissues were held at −20°C until they were processed. The tumor and normal mucosa were dissected away from the underlying stromal tissue and processed for isozyme analysis as noted below.

Isozyme analysis.—A pellet (0.1-0.2 ml) of cells or 0.5 g of tissue was placed in two volumes of homogenizing medium [0.01 *M* Tris-HCl (pH 7.5), 1 m*M* 2-mercaptoethanol, 1 m*M* EDTA], disrupted with a Dounce homogenizer at 4°C, and centrifuged (10,000×*g*, 45 min). Supernatants were stored at −70°C for less than 2 months (a temperature and time that preserve the activity of most enzymes). After thawing, supernatants were recentrifuged and subjected simultaneously to starch gel electrophoresis as generally described by Siciliano and Shaw (*22*). Four different buffer systems were used: 1) electrode consisting of 0.5 *M* Tris, 0.16 *M* EDTA, and 0.65 *M* borate (pH 8.0), and a gel consisting of 60 ml electrode buffer diluted to 600 ml with water with 20 mg NADP added after degassing; 2) an electrode consisting of 0.13 *M* Tris and 0.43 *M* citrate (pH 7.0), and a gel consisting of 40 ml of electrode buffer diluted to 600 ml with water; 3) an electrode consisting of 0.1 *M* Tris, 0.1 *M* maleic acid, 0.1 *M* EDTA, and 0.01 *M* $MgCl_2$ (pH 7.4), and a gel consisting of a 1:15 dilution of electrode buffer; and 4) an electrode consisting of 0.02 *M* Na_2HPO_4 and 0.046 *M* KH_2PO_4 (pH 6.5), and a gel consisting of a 1:10 dilution of electrode buffer. We swirled two Pasteur pipette drops of 2-mercaptoethanol into molten gels to restrict oxidation and secondary isozyme band formation during electrophoresis before we degassed the gels.

The isozymes and allozymes of the following enzymes were resolved on the following buffer systems: buffer system 1—CK, ME, PEP, PGD, G6PD, GOT, and ES; buffer system 2—ES, ADA, AK, GLO, and LDH; buffer system 3—PGM; and buffer system 4—ACP.

After electrophoresis, gels were sliced into as many as seven slabs, and on each slab an enzyme was identified from its histochemical stain. Recipes for enzyme stains have been described (*22, 23*). After being stained, gel slices were photographed (35-mm film) and discarded.

RESULTS

Genetic Signatures

Allozyme phenotypes of 13 polymorphic enzyme loci were studied in cell lines derived from colorectal adenocarcinomas and in lines derived from nonmalignant adult and fetal bowel mucosa (table 1). Examples of these phenotypes (except ACP) as resolved in this laboratory are published (*14*). ACP phenotypes are demonstrated in figure 1. Presence of the B-phenotype for *G6PD* in all cell lines indicates that they are free of HeLa cell contamination (*15, 25*). All SW samples were sent to us as lysed homogenates. With the exceptions of SW-742 and SW-802, the SW lines had different genetic signatures for the enzymes studied, indicating that they were derived from different individuals and are therefore of independent genetic origin and not cross contaminated. SW-742 and SW-802 have identical phenotypes for the 11 loci for which they were both examined. The probability is 0.042 of encountering

[a] The G6PD B phenotype was present in all cell lines, indicating their freedom from HeLa cell contamination (*15, 25*). Other polymorphic loci studied in each cell line, which are part of the cell line's genetic signature but which were uninformative in sorting out the cell lines because all lines had only the most common phenotype, were *GOT2, PEPA*, and *PEPC*. NR=not read. Phenotypes for *ADAR* were often not read because of either the lack of expression of the *ADA* locus or the production of ADA TCF, which obscured the electrophoretic typing of ADA (*26*). Phenotypes not read for other loci were not resolved from the material received for analysis.

[b] Probability of encountering the genetic signature of the cell line in human Caucasian population was calculated as the product of the frequencies of each phenotype at each locus (*14*).

this genetic signature by chance for the 11 loci in a Caucasian individual. For 12 lines of independent origin established in the same laboratory, the probability is 0.08 of finding two lines with the same genetic signature as that in SW-742 and SW-802 [for basis of these calculations, *see* (*14*)]. Since this is not too improbable (<0.05), these lines will be considered to be of independent origin in this report.

The eight COLO tumor lines carried in this laboratory were derived from 3 individuals. COLO 205 and COLO 206 were established from ascites cells sampled 2 weeks apart from the same individual; COLO 320 and COLO 321 were established from the same primary lesion of a second individual; COLO 394, COLO 396, COLO 399, and COLO 463 were established from one metastasis to the same iliac lymph node of a 3d individual. Genetic signature analyses confirm the independent origin of the 3 groups of cell lines. The five LS lines carried in this laboratory were derived from 2 individuals—LS123 and NB(LS123) were established from 1 person's primary adenocarcinoma and normal bowel mucosa, respectively; LS174T and LS180 were established from the primary colon adenocarcinoma, and NB(LS174T) was derived from the normal bowel mucosa of a 2d individual. Genetic signature analyses confirm the independent origin of these 2 groups of cell lines and their independence from the 3 COLO groups. The genetic signature analyses indicate that the remaining cell lines carried in this laboratory (HT-29, NB-M, NB-V, Hs0677Int, and Hs0074Int) are genetically independent of each other and the COLO and LS groups. As expected, cell lines derived from the same individual have identical genetic signatures (*11*).

The validity of these conclusions is further supported by the fact that the phenotype frequencies at each locus for all the cell lines derived from different individuals are not significantly different than the frequencies in the human Caucasian population.

Expression of Tissue-Specific Loci in Colon Tumor Cells and Their Subclones Grown Under Different Conditions

Seven isozyme loci (*LDHA, LDHB, ESB2, ESA4, CKB, ADAR*, and *ADAt*), which are variably expressed in different tissues, were examined in the reference colon tumor cell lines, LS174T and LS180. LS174T and LS180 expressed greater amounts of LDHA than of LDHB and had as much ESB2, ESA4, and CKB activity as did any cell line or human tissue studied in this laboratory (*see* figs. 2A and 2B, 3A-3C for examples). Six surgical specimens of nonmalignant human colon mucosal cells had the same pattern of isozyme expression. Identical gene expression patterns were observed in LS174T cells *a*) studied from TC 6-73, *b*) cultured in FBS-supplemented EMEM, Ham's medium F12, galactose-containing L-15 medium, or peptone-containing serum-free medium (*9*), *c*) harvested by trypsin or mechanical scraping (LS180), *d*) cultured on dishes or in a perfused hollow fiber culture system (*10*), and *e*) grown as tumors in nude mice or in cell cultures reinitiated from the mouse tumors after their trypsin disassociation. The expression of these loci was also the same in nine soft agar subclones of LS174T, nine plated subclones, 5 solid tumors produced in nude mice from five subclones, and in five subclones recultured after passage through nude mice. Therefore, the expression of these loci in LS174T is stable, homogeneous, and consistent with the colon mucosal origin of the cells.

The same cannot be said for ADA expression in the cell lines. Forms of ADA in LS174T cells varied in their expression under different culture conditions. The ADA structural locus is located on human chromosome 20 (*33*), is expressed variably in different tissues (*34-36*), and specifies the production of a low-molecular-weight enzymatic subunit that is responsible for the total ADA activity in cells (*26*). A second locus in human cells is active in certain tissues and produces a high-molecular-weight protein (TCF). Binding of TCF to the enzymatic subunit produces an electrophoretically slower form of the enzyme (*26*). When the structural *ADA* locus is active and TCF is not produced, the fast-migrating form of ADA (ADAR) is seen. Depending on the amount of TCF produced in cells, all or some of the ADA will appear as the slower migrating form (ADAt, *see* fig. 3B). LS174T and subclones, LS180 cells, and normal colon mucosal tissue produce ADAt. Insufficient TCF was produced to bind all the ADAR in all nude mouse solid tumors of LS cells and in one of four instances of LS cells grown in the hollow fiber system; consequently both isozymes appeared on the gels.

Isozyme Loci Expression

Various Colorectal Cell Lines Derived From Material in Different Malignant Stages

Data on isozyme expression in a series of colorectal cell lines derived from material of various malignant stages are listed in table 2. Only SW-742 and SW-1345 possessed the same isozyme pattern seen stably and homogeneously expressed in LS174T and LS180 tumor cells (LDHA > LDHB; ESB2, ESA4, and CKB were +++). While SW-742, like LS174T and LS180, was derived from a moderately invasive (Dukes B_2) and a relatively undifferentiated (Broders 2) colon adenocarcinoma, SW-1345 was derived from a more malignant rectal adenocarcinoma. Two other lines, SW-1116 and SW-1398, were derived from primary lesions of similar source and class as LS174T, but they had no detectable CKB activity. Lack of CKB expression cannot be accounted for by difference in the length of time in culture of SW-1116 and SW-1398. TC at which they were examined (TC 36 and 30, respectively) were neither higher than those for SW-742 and SW-1345 (TC 34 and 47) nor beyond the number of TC for which LS174T showed stable expression (TC 6-73).

Hs0677Int	A>B	–	–	+	–	+	24	FI	—	—
Hs0074Int	A>B	–	–	+	–	+	32	FI	—	—

[a] Activity was judged by intensity of histochemical staining of the gene product on starch gels after electrophoresis of cleared homogenate containing ≈10 mg protein/ml. +++ = greatest intensity observed in this laboratory; – = invisible gene product; + = barely visible gene product; and ++ = intermediate (between + and +++) intensity. For LDH activity, products of the *A* and *B* genes were compared as judged by skewing of the five banded LDH patterns in the direction of the *A* or the *B* gene product. Examples are shown in figs. 2 and 3.

[b] Only the earliest and latest passages tested are listed when several passages of a line were examined inasmuch as they all gave the same results.

[c] Malignant lines were derived from either colon (C) or rectal (R) adenocarcinomas; nonmalignant lines were derived from adult colon (C) or fetal intestine (FI) mucosal tissue. If the source of the line was the primary tumor, the source is *italicized;* ascites (A) and iliac node (N) indicate metastatic source.

[d] Broders class indicates percent of undifferentiated cells in the malignant tissue source (*37*): 1, ≈25%; 2, ≈50%; 3, ≈75%; and 4, ≈100%. Dukes class indicates extent of lesion invasion of the malignant tissue source (*38*): A, mucosa and submucosa; B, muscularis; B_1, into muscularis; B_2, muscularis penetrated; C, intestinal wall; C_1, limited to intestinal wall; C_2, extended through all layers with posterior node involvement; D, extent of metastasis includes other organs. ND = no data; — = not applicable.

In addition to CKB, activities of LDHA versus LDHB, and of ESB2 and ESA4 also varied among the colorectal tumor cell lines. Once again, no correlation was observed between isozyme expression and *a*) invasiveness or differentiation of the original tumor tissue, *b*) time in culture, *c*) colon or rectum tumor site, or *d*) derivation from primary or metastatic lesions. LDHA activity was not greater than was LDHA in SW-48, SW-1222, or SW-1345. All three lines were derived from rather malignant adenocarcinomas of both the colon and rectum. SW-837, SW-1417, SW-1463, and all eight COLO lines were derived from tumors at least as invasive as SW-48, SW-1222, and SW-1345 and had LDHA activity greater than that of LDHB. ESB2 was not expressed (–) or only weakly expressed (+) in several lines of a more malignant origin (SW-48 and the COLO series). However, ESB2 was well expressed (++) in SW-837 which was equivalent in TC and malignant nature to SW-48. Also, ESB2 was absent or only weakly expressed in SW-802 and LS123T—two lines originated from less invasive and differentiated tumors (both) or studied at a wide range of passage levels (LS123T). Similarly, weak or nonexistent ESA4 activity could not be related to the malignant status of the tumor source or the passage level of the cultured cells.

Stability of expression of the loci for the above-mentioned isozymes in the LS174T and LS180 cells grown under a wide variety of conditions is important in evaluating different expressional patterns observed in the other colorectal cell lines. Further evidence for the stability of expression of LDHA, LDHB, ESB2, ESA4, and CKB in the lines is provided by the data from the COLO cells. COLO 205 and COLO 206 were both establisned from 1 individual's ascites metastasis, obtained 2 weeks apart. The cell lines were maintained as separate cultures for 792 and 564 serial passages, respectively. Expressional patterns for the five stable isozymes were identical and included a unique pattern for LDH (fig. 3C). Similarly, COLO 320 and COLO 321 were derived from the same colon primary tumor and maintained separately. These cell lines have the same expressional pattern which differs from the COLO 205-COLO 206 set. The COLO 394, COLO 396, COLO 399, and COLO 463 lines were established from one iliac node metastasis and were carried in vitro separately. All four of these lines have the same expression patterns which differ from the other two COLO sets.

The inconsistency of the expression of the ADA isozymes observed in the LS174T and LS180 cells is also seen in the COLO sets. COLO 205 is essentially deficient in ADA expression, whereas COLO 206 is +++ for ADAR. Patterns of ADAt and ADAR expressions are reversed in COLO 320 and COLO 321, whereas the COLO 394-COLO 396-COLO 399-COLO 463 set displays several levels of ADA activity. Clearly, the ADA isozymes are not reliable markers for gene expression patterns in these cell lines.

Normal Colon Mucosa-Colon Adenocarcinoma Surgical Samples

The differences in expressions of the loci stably expressed in the colon tumor cell lines of independent origin suggest that these loci might be expressed differently either in the colon mucosae of different individuals or in adenocarcinomas that develop in different individuals. The data on isozyme expression for paired normal colon mucosa and adenocarcinoma surgical samples from 6 patients are shown in table 3. All of the normal colon mucosal samples were identical for every isozyme studied. Colon adenocarcinoma biopsy specimens had isozyme expressions that reflected the spectrum seen among the colorectal tumor cell lines.

Cell Lines Derived From Nonmalignant Colorectal Mucosa

General expressional patterns for cell lines derived from nonmalignant colorectal mucosae (table 2) are inconsistent with the patterns observed in normal bowel mucosa surgical samples (cf. with data in table 3). The only similarity of these lines with normal bowel mucosa is the greater expression of LDHA than of LDHB. However, with certain exceptions, e.g., SW-48, SW-948, and SW-1116 (this report) and choriocarcinoma cell lines (*36*), LDHA activity is usually greater than LDHB activity in mammalian cell lines. Lines derived from normal bowel mucosa and colon adenocarcinoma of the same patient have different expressional patterns [cf. paired NB(LS174T) with LS174T and NB(LS123) with LS123 (table 2)].

DISCUSSION

Cell Line Verification

The genetic signature analysis has been essential in determining the origin and integrity of cell lines maintained in the laboratory (*12-14*). Since gene expression patterns may differ in two cell lines derived from the same individual [cf. LS174T with NB(LS174T) and LS123 with NB(LS123), table 2], isozymes coded by multiple loci are less useful in that regard. The use of ADA expression for monitoring cell line contamination (*12*) is inappropriate, since we have shown that ADA

TABLE 3.—*Normal colon mucosa and adenocarcinoma:*[a] *Isozyme expression*

[a] Six paired surgical specimens were used, all of which had a greater expression of LDHA than of LDHB.
[b] — = not applicable. *See* fn *d*, table 2, for definition of terms.

isozyme expression varies considerably with culture conditions. Incorporation of ADAR phenotypes in the genetic signature is appropriate, when expressed, since it and other allozymatic markers have proven stable in cultured cells (*13*, *25*), varying only at mutational frequencies in isolated subclones (*39*, *40*).

Our conclusion that SW-742 and SW-802 have independent origins, even though they have the same genetic signature ($P=0.08$) appears justified because of their different expressions of ESB2, ESA4, and CKB, which we have shown to be stably expressed in the colorectal adenocarcinoma cell lines through the TC at which SW-742 and SW-802 were examined.

Isozyme Expression

Five tissue-specific isozymes maintain stable expression in colorectal tumor cell lines through a wide range of serial passages and culture conditions and in multiple cell lines from the same tissue sample. A range of expressional patterns for these loci occurs in lines of independent origin and in colon adenocarcinoma surgical samples. We conclude from these observations that colorectal adenocarcinomas differ from one another in their gene expression characteristics. When one considers the facts that these isozyme loci have been shown to be under both stage and tissue-specific regulation [*see* review (*41*)] and that cell lines lacking their expression have been shown to contain the chromosomes known to bear the structural loci (*5*), the differences in gene expression characteristics are viewed as having a regulatory rather than structural basis. Colorectal adenocarcinoma cell lines reflect the diversity in isozyme expression in tumors and represent important and useful models for the disease.

The question of whether the gene expression pattern in a tumor cell line reflects the pattern in the solid tumor from which it was derived or represents a subpopulation of cells selected by culture from the tumor cannot be answered at this time. Experiments are in progress to compare the expressional patterns in solid tumors with those of lines and soft-agar clones established directly from them (*42*). We emphasize caution in this area because we observed different expressional patterns among cell lines derived from normal bowel mucosa while several surgical mucosal samples exhibited identical gene expression patterns. These results also indicate that the normal bowel cell lines studied are not adequate models for normal bowel mucosa.

Recent studies have shown that solid tumors and tumor cell lines are composed of subpopulations that are heterogeneous with regard to metastatic potential (*43*, *44*), responses to chemotherapeutic agents (*45–47*), growth rate and differentiation (*48*), karyology (*49*), and antigenic composition (*50–52*). Our results suggest that the gene expression patterns of colorectal adenocarcinoma cell lines may be the same as patterns of the original tumors, and individual colorectal tumors may not be extensively heterogeneous for these properties. This suggestion is supported by the observation that CKB activity was not detectable in two tumor biopsy specimens (from patients #1 and #5; table 3). Dilution experiments (data not shown) indicate that as little as 5% of full CKB cellular activity can be detected on starch gels after electrophoresis. It would appear, therefore, that if some cells in the tumors were producing high levels of CKB activity, they probably represent less than 5% of the tumor population.

Other indirect evidence that the gene expression patterns of the tumor cell lines may actually represent the isozymes in the original tumors is the inability to correlate expressional differences with the TC in culture. Also, similar patterns were observed for the stable isozymes when independent tumor cell lines were compared with colon adenocarcinoma surgical samples. For example, similar gene expression was observed for *a*) SW-1116, SW-1398, SW-1417, and SW-1463 and the surgical specimen from patient #1; *b*) SW-403, SW-742, SW-948, and LS174T and the surgical specimens from patients #2 and #3; *c*) COLO 320, COLO 321, and HT-29 and the surgical specimens from patients #4 and #6; and *d*) SW-48 and the surgical sample from patient #5. While our data are conclusive for the tumor-to-tumor variations in gene expression, preliminary data and speculation indicate that cell-to-cell variations for isozyme expression with these tumors may be minimal.

No correlation was observed between isozyme gene expressions in the tumor cell lines and either the extent of invasion (Dukes classification) or the level of differentiation (Broders grade). Thus development of tumors from specific cell types originally present in normal bowel mucosa may be more important in isozyme gene expression differences than changes in expression to fetal forms of isozymes (*53*). Such a phenomenon would also account for the tumor-to-tumor variations observed in the expressional patterns. Further experiments are needed to understand these basic biological characteristics of colorectal cancer, which may be useful in biochemical classification of colorectal tumor subtypes, in the design of therapy modes, and in management of colon cancer.

Figures 1-3.—Zymograms of representative isozymes studied. Origins are marked "o" at the *right*; anodes are toward the top, cathodes toward the bottom.

Figure 1.—ACP1. Positions of the products of the *a* allele (single cathodal band) and *b* allele (double anodal bands) are indicated to the *left*. These are the expected positions of these gene products after electrophoresis on a pH 6.5 phosphate buffer system lacking citrate (*24*). Both *a,b* and *a* phenotypes are readily distinguishable.

Figure 2.—ES run on the Tris-citrate, pH 7 system and stained with methyl umbelliferyl acetate (fig. 2A) and on the Tris-Versene-borate, pH 8 system stained with a diazonium salt (fig. 2B). Positions of the ES isozymes under study are indicated to the *left* of each figure and are consistent with the findings of Coates et al. (*27*). Sample order on both gels is 1: COLO 320; 2: Hs0677Int; 3: Hs0074Int; 4: LS174T; 5, 6: two subclones of LS174T re-established in culture after forming solid tumors in nude mice; and 7: LS123. ESD phenotypes are part of the genetic signature analysis since they are polymorphic (*28*) and constitutively expressed in all tissues and cell lines studied (*29*). ESB2 and ESA4 are differentially expressed in different human tissues (*27*) and are seen on these gels only in LS174T and its subclones after passage through nude mice.

Figure 3.—Isozymes after electrophoresis and histochemical staining of 1: LS174T grown in the perfused hollow fiber system; 2: COLO 205; 3: COLO 396; and 4-6: three subclones of LS174T. 3A) Fast-migrating CKB is expressed in several different human tissues (*30, 31*). It is clearly expressed in the LS174T line and its subclones and is absent in COLO 205 and COLO 396. The more slowly migrating zones are AK activity, which also stain but are not well resolved on this buffer system. 3B) ADAR and ADAt are indicated on the *left*. These ADA isozymes are expressed in different tissues, as described in the text. Nearly all the ADA of LS174T cells is ADAt, whereas it is ADAR in both COLO lines due to their lack of TCF expression (*26*). 3C) Five common forms of LDH are the result of the two differentially expressed genetic loci *A* and *B* (*32*). The five are electrophoretically separable tetramers. Positions of the A and B homotetramers are indicated on the *left*. A slightly greater expression of LDHA than of LDHB is indicated in most of the cell lines by a greater staining intensity of the more cathodally positioned isozymes. COLO 205 is remarkable due to its exclusive expression of LDHA.

Coffee Drinking and Cancer of the Lower Urinary Tract[1,2,3]

Alan S. Morrison, *M.D.*,[4] **Julie E. Buring**, *M.S.*,[4] **Wendy G. Verhoek**, *M.S.*,[5] **Kunio Aoki**, *M.D.*,[6] **Ian Leck**, *M.B.*, *Ph.D.*,[5,7] **Yoshiyuki Ohno**, *M.D.*,[6] *and* **Koji Obata**, *M.D.*[8,9]

ABSTRACT—The relation of coffee drinking to the incidence rate of cancer of the lower urinary tract ("bladder cancer") was evaluated. Broadly based series of cases and series of controls drawn from the general population of each area were assembled and interviewed in Boston, Massachusetts (587 cases, 528 controls), Manchester, England (541 cases, 725 controls), and Nagoya, Japan (289 cases, 586 controls). Compared to drinkers of an average of less than 1 cup of coffee per day, those who drank more had a relative risk of bladder cancer estimated as 1.0 (0.8-1.2, 95% confidence interval). With adjustment for cigarette smoking habits, only small and irregular changes in risk were seen with increasing frequency of coffee consumption. Duration of coffee drinking showed little relation to risk of bladder cancer. Apparent associations of coffee drinking and bladder cancer may be due to incomplete control of the effect of cigarette smoking. If there is a true association of coffee drinking and bladder cancer it is likely to be weak.—JNCI 1982; 68:91-94.

A positive association between coffee drinking and cancer of the lower urinary tract has been suspected for nearly a decade (*1*). Additional studies also suggest an association but the question of whether there is a causal link has not been resolved (*2-8*). Here we present data from an international collaborative case-control study of the relation of coffee drinking to the incidence of cancer of the lower urinary tract.

METHODS

The study was done in three areas: The Boston, Massachusetts, Standard Metropolitan Statistical Area; six contiguous health districts in greater Manchester, United Kingdom (Central and South Manchester, Oldham, Stockport, Tameside, and Trafford); and Nagoya, Japan, and ten of its surrounding cities and towns. An attempt was made to assemble a complete series of incident cases in each area during a defined study period, which was March 1976 through May 1977 in Boston, October 1976 through September 1978 in Manchester, and January 1976 through December 1978 in Nagoya. To be eligible a person had to have had an initial diagnosis of a primary neoplasm of the lower urinary tract (bladder, ureter, renal pelvis, or urethra) during the study period and to be at least 21 years old and a resident of the study area at the time of diagnosis. Persons over 89 years old at the time of diagnosis were not eligible for interview.

Case identification was accomplished primarily through hospitals. Tumors throughout the histologic spectrum from papilloma to invasive neoplasia were included. For brevity, the term "bladder cancer" is used as a synonym for neoplasms of the lower urinary tract (*9*). The number of identified patients less than 90 years old was 741 in Boston, 577 in Manchester, and 348 in Nagoya. Of these patients, 95% had bladder tumors and 83% were specified as having squamous or transitional cell carcinomas.

Controls were selected by random sampling procedures from electoral registers for each study area. Each of these registers is updated annually and is believed to contain a nearly complete list of adult residents. Sampling methods were designed so that each control series would have an age and sex distribution similar to that of the respective series of cases. The number of controls was 677 in Boston, 817 in Manchester, and 735 in Nagoya.

The specific methods of identification of the subjects in Boston have been described (*9*). Cases and controls were selected in Manchester and Nagoya as follows: In Manchester, periodic searches for cases were made with the use of pathology log books or reports on all surgical specimens at nine of the ten hospitals with pathology departments in the study area. The discharge summaries received by the North Western Regional Health Authority for all ten hospitals also were searched, as were the records of the North Western

Regional Cancer Registry, where all cases in residents of the study area should have been registered regardless of their place of treatment. Controls were selected from the 1977 and 1978 electoral rolls for the cities and towns surveyed. Because these rolls do not indicate residents' ages, it was impossible to select directly a series of controls with the desired age distribution. Therefore, the selection of the controls was done in two phases. Initially, six names were sampled for each of the first 464 cases identified, with matching by sex but not by place of residence. An attempt was made to determine the dates of birth of the 2,784 people identified. In most instances the information was obtained by interview of the subject or a household member; otherwise, the Family Practitioner Committee for the relevant area was asked. (Each Family Practitioner Committee keeps records of all residents of its area who have registered for general medical care within the National Health Service.) Of the 2,745 potential controls for whom the dates of birth were learned, 817 then were subsampled, with a probability based on present age, as eligible for interview.

In Nagoya, virtually all patients with urinary tract tumors are referred for definitive diagnosis and treatment to hospitals with staff urologists (Obata K: Unpublished data). There were 19 such hospitals in the study area. The responsible urologist in each of these hospitals reported all patients with tumors of the lower urinary tract to the project staff. The selection of controls was based on the 1976, 1977, and 1978 electoral registers for the communities that comprised the study area. The case and control series were similar with respect to residence in Nagoya City versus one of the surrounding communities but were not matched more closely on residence within these broad areas.

As many eligible subjects as possible were interviewed. If a subject was too ill for interview, could not be contacted, or had died, an attempt was made to interview a proxy (i.e., a relative or friend familiar with the subject's background and habits). Interviews were obtained for 597 patients (81% of the total eligible) and 544 controls (80%) in Boston, 555 patients (96%) and 735 controls (90%) in Manchester, and 293 patients (84%) and 589 controls (80%) in Nagoya. In general, interviews were done at subjects' homes. The major exception occurred in Nagoya, where 87 patients were interviewed as inpatients and 107 were interviewed during an outpatient visit. In Manchester, 54 patients were interviewed as inpatients at the request of the responsible physician. In all three study areas, some subjects were interviewed at another location, such as a place of employment, or by telephone.

To the extent compatible with differences in language and customs, the interview schedule was standardized among the study centers. Questions were included on many known or suspected causes of bladder cancer (*9*). With respect to coffee consumption, subjects were asked whether they had ever drunk coffee. Those who had were asked the amount they had drunk on the average, when they began drinking coffee, the period in which they were drinking the most coffee and how much that was, what their current consumption of coffee was, and, if they had stopped drinking coffee, when. Those whose current consumption of coffee was at least 2 cups per week were questioned in detail about the amount of coffee consumed according to type (ground and brewed or instant; in Boston and Nagoya, use of regular or decaffeinated coffee as well). Current consumption was defined as consumption 1 year before interview or in the calendar year before diagnosis for patients interviewed more than a year after diagnosis.

Results are given primarily in terms of the "relative risk," an estimate of the ratio of the bladder cancer incidence rate among drinkers of a specified amount of coffee compared to persons drinking less than 1 cup per day. Trends in relative risk were similar for three measures of the frequency of coffee drinking—average, current, and maximum. Therefore, this presentation focuses on the average frequency. Relative risks presented are simultaneous maximum likelihood estimates (*10*). Variables controlled are indicated in context and included age (<65, 65-74, and ≥ 75 yr), sex, study area, and cigarette smoking habit (never smoked, ex-smoker, or current smoker of <1, 1, 2, or ≥ 3 packs/day). Occupational history (*9*) was not controlled, since adjustment for this variable (in men) had no effect on the respective relative risk estimates. The analysis was restricted to subjects for whom both coffee drinking and cigarette smoking habits were known.

RESULTS

Compared to subjects who drank an average of less than 1 cup of coffee per day, those who drank more had a relative risk estimated as 1.0 (0.8-1.2, 95% confidence interval), with adjustment for age, sex, study area, and cigarette smoking. In subjects who never had smoked cigarettes, the relative risk (adjusted for age, sex, and study area) was estimated as 1.0.

The distributions of cases and controls according to average daily coffee consumption are given in tables 1-3. Generally, the distributions of coffee consumption were similar between cases and controls, and the differences present do not appear to follow a regular pattern. However, there was a moderate excess of cases compared to controls among both men and women in Boston who drank 6 or more cups per day.

With age and cigarette smoking controlled, a regular increase in relative risk with increasing coffee consumption was not apparent in any of the study areas. Most of the relative risk estimates were close to 1. The highest relative risk observed, 1.9, was that for men in Nagoya who drank 5 or more cups of coffee per day. However, this estimate was based on only 13 heavily exposed subjects.

In Manchester and Nagoya, there were substantial numbers of subjects who consumed small amounts of coffee, less than a cup per day but at least a cup per year. At these low levels of consumption, no regular

TABLE 1.—*Percentage distribution of cases and controls and relative risk of bladder cancer according to average frequency of coffee drinking by sex in Boston*

[a] Adjusted for age and cigarette smoking.

pattern of increasing relative risk in relation to increasing intake was apparent.

The relation of coffee drinking and bladder cancer was similar for ground versus instant coffee. No large or regular changes in relative risk were associated with increasing duration of coffee drinking.

Telephone interviews, interviews with proxies, and interviews rated "unreliable" by the interviewer were considered to have yielded relatively poor information. In this category there were 130 cases and 117 controls in Boston, 113 cases and 68 controls in Manchester, and 31 cases and 89 controls in Nagoya. With these cases excluded, the relative risk of bladder cancer among drinkers of a cup or more of coffee per day was virtually unchanged.

DISCUSSION

The results of the present study indicate that coffee drinking confers little or no risk of bladder cancer. People who drank an average of a cup or more of coffee per day had a risk similar to that of people who drank less. There was little evidence of an increase in risk with increasing coffee consumption. Other aspects of coffee consumption such as duration of use or type of coffee used also showed little relation to risk of bladder cancer.

A number of previous studies of coffee drinking and bladder cancer have been done in the United States. In a study in the Boston area, Cole (*1*) reported relative risks of 1.3 in men and 2.5 in women for drinkers of 1 or more cups of coffee per day compared to those who drank less. A positive association also was observed in another study that was limited to women in the Boston area (*2*). Fraumeni et al. (*3*) reported relative risks of 2.0 in men and 1.2 in women for drinkers of coffee relative to nondrinkers. Bross and Tidings (*4*) reported a weak positive assocition for men and a weak inverse one for women. Wynder and Goldsmith (*5*) found positive associations in both men and women; the relative risk appeared slightly higher for men. Mettlin and Graham (*6*) reported a positive association between coffee drinking and bladder cancer in men, but little relation in women. Two case-control studies have been reported from Canada. Morgan and Jain (*7*) observed little relation of coffee drinking and bladder cancer in either men or women. Howe et al. (*8*) observed a positive association among men but not among women.

On the basis of the essentially "negative" results of the present study and the low and inconsistent relative risks observed previously, it appears that if there is a relation between coffee drinking and bladder cancer, it is weak. Moreover, we believe that the positive associations reported may have been in part the result of incomplete control of the effect of cigarette smoking.

Cigarette smoking is an important risk factor for bladder cancer, and smoking is correlated strongly with coffee drinking. Therefore, the cigarette smoking habits of subjects should be controlled in an analysis of coffee drinking and bladder cancer. In each of the studies cited except one (*7*), some adjustment for smoking was made. However, smoking might not have been con-

[b] Value pertains to drinkers of ≥2 cups of coffee/day.

trolled completely due to use of an insufficient number of smoking strata in the analysis (*11*). Given a limited amount of data, the degree of stratification necessary for adequate control of smoking might not be feasible. Several investigators (*2, 4–6*) have used from two to four smoking strata. In contrast, estimates in the present study summarize the coffee-bladder cancer relation over six categories of smoking.

Incomplete control of smoking also might be a consequence of random inaccuracies in the smoking histories available. If the smoking history is unreliable, it will fail to reflect fully the hazard of smoking and its association with coffee drinking, so that complete control of the effect of smoking will not be obtained (*12*). An apparent relation of coffee drinking and bladder cancer could stem from this source, which is not related to response bias.

The conditions that could lead to distortion of the coffee-bladder cancer relation by smoking appear to be especially marked in the United States. The extent of such distortion would depend in part on the disparity in smoking habits between drinkers of large and of small amounts of coffee. In the male control series in the Boston center of the present study, the proportion of heavy smokers (≥2 packs/day) was six times greater among drinkers of 5 or more cups of coffee per day than among drinkers of less than 2 cups per day. In contrast, the proportion of heavy smokers was only about twice as high among drinkers of large amounts compared to small amounts of coffee in Manchester and Nagoya. The distortion related to cigarette smoking also would depend on the actual proportion of heavy smokers among drinkers of large amounts of coffee. This proportion was about twice as high in Boston as in Manchester or Nagoya.

Finally, cigarette smoking is more prevalent in men than in women. Therefore, a secondary association of coffee drinking and bladder cancer might be expected to be stronger in men. Most studies have, in fact, found a stronger positive association in men than in women.

Noncontraceptive Estrogen Use and the Occurrence of Ovarian Cancer [1,2,3]

Noel S. Weiss, *M.D., Dr.P.H.*, [4,5,6] **Joseph L. Lyon**, *M.D., M.P.H.*, [7] **Sarala Krishnamurthy**, *M.B.B.S., M.D.*, [5] **Scott E. Dietert**, *M.D.*, [5] **Jonathan M. Liff**, *M.S.*, [5] *and* **Janet R. Daling**, *Ph.D.* [4,5]

ABSTRACT—Female residents of six counties in Washington and Utah in whom ovarian cancer was diagnosed during 1975–79 were interviewed concerning prior use of noncontraceptive estrogens. Interviews with a random sample of women drawn from these counties were obtained for comparison. Taken as a whole, women with epithelial ovarian tumors reported estrogen use for 1 year or more somewhat more often than did controls [relative risk (RR) = 1.3, 95% confidence interval (CI) = 0.9–1.8]. The proportion of women who had used estrogens varied according to the histology of their tumor; notably, of 17 women with endometrioid tumors, 12 had used estrogens (RR = 3.1, 95% CI = 1.0–9.8). The excess risk of endometrioid carcinoma related to estrogen use was not further increased when these hormones were taken for long durations, in high doses, or proximate to the time of diagnosis. Neither was there any evidence of increased risk from estrogen use in the small group of women with clear cell tumors, a histologic tumor type believed to be closely related to endometrioid carcinoma. Thus the observed association between menopausal estrogen use and the occurrence of ovarian endometrioid tumors should be interpreted cautiously until the results of additional studies are available.—JNCI 1982; 68:95–98.

The patterns of occurrence of malignant tumors of the ovary, endometrium, and breast have a number of common features. The incidence of each tumor type tends to be higher in Western than in Eastern cultures and, within the West, higher in white women than in nonwhites (*1*). Though their incidence rises rapidly during late reproductive life, after that time it fails to show the age-related exponential increase that is characteristic of many other tumors (*1*). Ovarian, endometrial, and breast cancer are all less common among women who have borne children than among nulliparous women (*2–5*). Thus it is likely that these 3 neoplasms share one or more etiologies. Since use of noncontraceptive estrogens is a strong risk factor for endometrial cancer (*6*), and possibly a weaker one for breast cancer as well (*7–9*), we conducted a study to determine what, if any, role estrogens play in the genesis of ovarian cancer.

METHODS

With the assistance of population-based cancer reporting systems, we identified all white females ages 50–74 years with ovarian cancer who were *a*) residents of King and Pierce Counties (Washington) and diagnosed during 1976–79, and *b*) residents of Salt Lake, Weber, Utah, and Davis Counties (Utah) and diagnosed during 1975–77. Using the original pathologists' diagnoses as a criterion, we excluded tumors of sex cord-stromal or germ cell origin; this left only women bearing "epithelial" tumors. In the Washington counties only, 22 women with "borderline" tumors (i.e., lesions that lacked stromal invasion but had an otherwise malignant appearance) were identified by the reporting system. Because of the potential of borderline tumors for metastasis, these women were included in the analysis.

Between 1 and 18 months after diagnosis, each woman was approached through her physician for an interview at home. The response status of the women with cancer is shown in table 1. Of those who were not interviewed, about two-thirds had died before or during our efforts to contact them. The interview itself covered the woman's menstrual and reproductive history, with particular attention to the use of contraceptive and noncontraceptive estrogens. In an effort to aid recall, we used a color display of commonly used estrogen preparations.

To identify and interview women against whom the patients with cancer could be compared, we did household surveys in both areas. In the Washington counties, this was accomplished by standard area sampling methods in 1976, 1977, and 1979 (*10*). In Utah in 1977, a systematic sample of telephone numbers was selected from the directories serving the four counties. The final two digits were replaced with a number chosen at random, and each resulting telephone number was dialed up to six times. If a household was reached, we sought to obtain a census; this was possible for 91% of households. If a women resided there who was 35–75 years of age, we sought to interview her at home.

The average interval from the diagnosis of ovarian cancer until the study interview was nearly 1 year.

ABBREVIATION USED: RR = relative risk.

TABLE 1.—*Response status of women with ovarian tumors*

Cases[a]	No. of subjects
Washington counties, diagnosed 1976–79	298
Women for whom no interview was obtained (physician or patient refused interview, moved, or died)	129
Subjects interviewed	169
Utah counties, diagnosed 1975–77	74
Women for whom no interview was obtained	36
Subjects interviewed	38
Total No. of subjects interviewed	207

[a] White women ages 50–74 yr had epithelial ovarian tumors.

Thus only those control subjects ages 51–75 at the time of interview are included in the analysis, so as to conform more closely to the age range of the women with cancer. Information on estrogen use among controls during the year before interview was deleted to parallel the deletion of information on cases after diagnosis. We also excluded potential controls who reported having undergone a bilateral oophorectomy more than 1 year before interview. The selection of controls is summarized in table 2.

The proportion of women reporting use of noncontraceptive estrogens (defined as use for ≥1 yr) varied little during the course of the study. In the Washington counties, for example, the proportion of users among controls interviewed in 1976, 1977, and 1979 was 45.0, 47.5, and 44.4%, respectively. Variables that did correlate with estrogen use were age, hysterectomy status, and income (median family income of census tract of residence). Since the distribution of income level was similar in women with and without ovarian cancer, our case-control comparisons regarding history of estrogen use are standardized only for age (50–54, 55–64, and 65–74 yr), presence of a uterus, and state of residence (Washington or Utah).

TABLE 2.—*Response status of potential control subjects*

Controls	No. of subjects
Washington Counties[a]	1,271
Subjects excluded	
No interview obtained	99
<51 yr of age	463
Nonwhite women	43
Bilateral oophorectomy ≥1 yr before interview	116
Subjects interviewed	550
Utah Counties	111
Subjects excluded	
No interview obtained	12
<51 yr of age	28
Bilateral oophorectomy ≥1 yr before interview	8
Subjects interviewed	63
Total No. of subjects interviewed	613

[a] Women ages 36–74 yr were identified in three sample surveys.

[b] White women ages 36–75 yr were identified in the 1977 survey.

This study directly measured the relative proportion of estrogen users and nonusers among patients and controls, i.e., the relative odds of estrogen use. Because the incidence in users relative to nonusers (i.e., RR) is accurately estimated by the relative odds, and because it has greater intuitive meaning, the results will be expressed in these terms.

RESULTS

As a group, women with epithelial ovarian tumors reported taking estrogens (for ≥1 yr) to a somewhat greater extent than did control women (table 3). The small group of women diagnosed as having endometrioid tumors was responsible for a part of this excess; 12 of the 17 women in the group had taken estrogens, giving an RR of 3.1 ($P=0.05$). Among women diagnosed as having one of the other histologic tumor types, women with serous tumors had used estrogens more than had controls ($RR=1.6$; $P=0.07$), whereas those with mucinous tumors had used them less often ($RR=0.7$; $P=0.27$).

The estrogen-endometrioid tumor association was present in both states (8 of 13 Washington patients and 4 of 4 Utah patients had used estrogens for ≥1 yr) and was present whether or not the women retained her uterus and whether or not she had given birth to a child. The association was not further strengthened when only long durations or higher doses of estrogen use were considered, because patients and controls who reported taking estrogens had similar patterns of doing so (table 4). The small excess risk observed for all histologic tumor types combined also was not influenced further by the duration (54 cases observed with duration >5 yr, 52.3 expected on the basis of controls who were users), amount, or timing of estrogen use. In contrast to the findings of an earlier study

TABLE 3.—*Use of noncontraceptive estrogens among women with various histologic types of ovarian cancer and among controls*

Histologic type	Estrogen users, %[a] No. of patients	RR[b]	95% confidence interval[c]
All cases[d]	49.8 (205)	1.3	0.9–1.8
Serous	54.2 (72)	1.6	1.0–2.6

Controls	44.2 (611)	—	—

[a] Users for ≥1 yr.

[b] Relative to risk of 1.0 in estrogen nonusers and users of <1 yr. Standardized for age, hysterectomy status, and state of residence (Washington, Utah) by the method of Mantel and Haenszel (*11*).

[c] Approximate, according to the method of Miettinen (*12*).

[d] Epithelial tumors only; excludes tumors of germ cell or sex cord-stromal origin.

[e] Includes one case each of "adenocarcinoma with squamous metaplasia" and "adenosquamous" cancer.

[f] Primarily tumors labeled as "papillary," "adenocarcinoma," or "carcinoma" without further specification.

TABLE 4.—*Pattern of noncontraceptive estrogen use among women with endometrioid tumors*

Pattern of use	No. of estrogen users	
	Observed[a]	Expected[b]
Total duration >5 yr	7	6.5
First use >5 yr before diagnosis	9	8.5
Use during year before diagnosis	6	8.1
Average daily dose >1.0 mg	9	8.4
Ever used diethylstilbestrol	0	1.0

[a] No. = 12.

[b] Based on the experience of those control subjects who used noncontraceptive estrogens, standardized for age and state of residence.

(*13*), use of diethylstilbestrol was related neither to the occurrence of all epithelial types (observed:expected = 3:5.4) nor to that of endometrioid tumors (observed:expected = 0:1.0). We interviewed eight women who had clear cell tumors, a tumor type believed to be histogenetically related to endometrioid tumors (*14*); only 2 of the 8 reported having used estrogens (RR = 0.5; $P = 0.4$).

The entity "endometrioid" carcinoma has been included for less than 20 years in widely recognized schemes for classification of ovarian tumors. Thus we were concerned as to the accuracy of the diagnoses of this histologic type of tumor which were made in individual hospital laboratories and which had not been reviewed by standard criteria. Because of this concern, we procured the original slides of the 13 tumors for the Washington cases labeled as endometrioid. Two of us (S. K. and S. D.) reviewed these slides along with those from tumors of 10 estrogen users and 10 estrogen nonusers selected at random from the other Washington cases; the reviewers had no knowledge of the original diagnosis or the history of estrogen consumption. The criteria used to classify tumors as endometrioid were those of Long and Taylor (*15*) and of Serov et al. (*16*). The histology of an ovarian tumor often is not homogeneous, so, though we classified each one according to its major component, the presence of endometrioid characteristics as a minor component was specified as well. The results of our review are shown in table 5. The original diagnosis of endometrioid carcinoma was confirmed in 10 of 13 cases, and an endometrioid pattern present to a minor degree was observed in the remaining 3. Estrogens had been used in 7 of the 10 confirmed cases and in 1 of the 3 cases with a minor endometrioid component. The agreement of the review diagnosis with the original diagnosis of "nonendometrioid" carcinoma varied according to whether the patient had previously used estrogens: In the absence of exogenous estrogen exposure, the degree of correspondence was high, whereas in tumors of 5 of the 10 women with a history of estrogen use, at least a minor degree of endometrioid features was exhibited.

TABLE 5.—*Results of histologic review of slides from cases of ovarian cancer in western Washington*[a]

Original diagnosis	Diagnosis from slide review			
		Other epithelial		
	Endometrioid	Endometrioid component present	Endometrioid component absent	Total
Endometrioid	10	3	0	13
Other epithelial				
History of estrogen use	2	3	5	10
No history of estrogen use	1	0	9	10

[a] *See* text for criteria for selection of case groups.

DISCUSSION

Several features of the association found here between the use of noncontraceptive estrogens and the incidence of ovarian endometrioid tumors suggest that the association may be real. The estimated risk to users relative to nonusers is high ($\approx$3), and the diagnoses upon which this estimate is based appear accurate. In several areas of the United States, the *reported* incidence of endometrioid tumors increased during the early 1970's (*17*) in parallel with the increasing use of noncontraceptive estrogens. (However, since acceptance among pathologists of endometrioid tumors as a histologic entity was also growing during this period, the *true* increase in incidence was undoubtedly smaller than that reported). Also, as their name suggests, these lesions are similar in appearance to carcinoma of the endometrium, a tumor whose relationship to exogenous estrogens has been well documented (*6*).

Nonetheless, some aspects of this study require caution when the results are interpreted. First, a sizable fraction (44%) of the women with cancer who were eligible to take part in the study were not interviewed, the primary reasons for noninterview being death and terminal illness. While this degree of nonresponse could bias the risk estimates in either direction, it is more likely to have forced them higher: Estrogen users were possibly diagnosed earlier in the course of their disease than were nonusers (estrogen users were likely to have received regular gynecologic examinations), and so it is possible that a disproportionately high percentage of estrogen-using patients were able to provide an interview. However, while the small excess risk for nonendometrioid epithelial tumors might to some extent be explained by this bias, it is not likely to account for the association between estrogen use and endometrioid tumors: The magnitude of that association was much stronger, and the proportion of women with endometrioid carcinoma who were not interviewed was lower (5/22 = 23%).

Second, at least some inaccuracy was likely in the interview information on oophorectomy status which served as the basis for exclusion of individual control subjects. *a*) Some potential controls who claimed that both ovaries had been removed, in truth, had one or both retained, but nonetheless were excluded from the analysis. *b*) Contrariwise, some women who believed that one or both of their ovaries were present, in truth, had no ovarian tissue left, and yet were included as control subjects. Because having undergone a bilateral oophorectomy is a strong predictor of having used estrogens, an artificially positive association of estrogen use and ovarian cancer could have resulted if errors of type *a*) above exceeded those of type *b*). However, since self-reported oophorectomy status has been found to correspond closely to information obtained from the women's hospital records at the time of surgery (*18*), the magnitude of any bias of this sort is likely to have been small.

Third, though the incidence of endometrial cancer increases steadily with increasing duration of noncontraceptive estrogen use (at least through the first 10-15 yr of use) (*19*), we did not find such increases to be true for ovarian endometrioid tumors (table 4). Finally, there was no evidence for the association of estrogen use and the incidence of ovarian clear cell tumors, the histologic type thought to be closely related to endometrioid tumors in terms of histogenesis.

Even if the use of menopausal estrogens were truly associated with the incidence of ovarian endometrioid tumors, it is conceivable that the overall incidence of ovarian tumors in estrogen users is not altered. For example, it is possible that, in response to the presence of exogenous estrogens, epithelial ovarian tumors that arise through other etiologic pathways are stimulated to exhibit a glandular (endometrioid) component. Or, if some ovarian tumors begin as highly differentiated lesions and over time become increasingly less differentiated, then the estrogen user, who may have her cancer diagnosed more promptly than the nonuser, will tend to have a more highly differentiated tumor (e.g., endometrioid) at diagnosis.

However, for either or both of the above hypotheses to fully explain the estrogen-endometrioid tumor association, the risk to estrogen users relative to that of nonusers for ovarian epithelial tumors *other than* endometrioid must be less than 1.0: Each hypothesis provides for no excess cases of ovarian cancer as a result of estrogen use, so that the excess "risk" seen for endometrioid tumors must be balanced by a deficit in risk for the others. Except for the relatively small group of women with mucinous tumors, no indication of such a deficit was present in our data.

We believe that another, more plausible, explanation for the observations is that estrogen use does lead to an increased incidence of endometrioid tumors but not of other ovarian epithelial tumors, and that the excess risk for the latter group is due to the inclusion of endometrioid tumors not recognized as such (*see* table 5). Nonetheless, the data we have presented here in support of this interpretation are far from definitive. A larger case-control study, with a histologic review of a larger proportion of the cases, will be needed before much faith can be put in any of these interpretations.

Multiple Marker Evaluation in Human Prostate Cancer With the Use of Tissue-Specific Antigens[1, 2, 3]

M. Kuriyama,[4] M. C. Wang,[4] C. L. Lee,[4] C. S. Killian,[4] L. D. Papsidero,[4] H. Inaji,[4] R. M. Loor,[4] M. F. Lin,[4] T. Nishiura,[5] N. H. Slack,[6] G. P. Murphy,[6] *and* T. M. Chu[4,7,8]

ABSTRACT—Serum prostate-specific antigen and prostatic acid phosphatase were simultaneously evaluated in 22 healthy males, 29 patients with benign prostatic hypertrophy, and 192 patients with prostate cancers at various stages as well as in 30 patients with cancers other than prostate cancer. Both markers were quantitated by specific sandwich-type, enzyme-linked, immunocorbent assays with the use of specific antiserum reagents. Serum assays revealed a discordance between these two markers; thus expressions of these two biochemically and immunologically distinct prostate-specific proteins may reflect different aspects in the biology of prostate cancer. A combination test with the use of 7.5 ng of prostate antigen and 15.5 ng of prostatic acid phosphatase/ml of serum, respectively, as cutoff values resulted in a positive detection rate of 58% for prostate cancers of stages A (7/12) and B (21/36) each, 68% for prostate cancer of stage C (19/28), 92% for prostate cancer of stage D (108/118), and only 10% for benign prostatic hypertrophy (3/29). None of 52 other cancers or healthy controls was registered as positive. This study demonstrates that a multiple marker test of tissue-specific antigens can be of an additive value in the immunodiagnosis of cancer and may be a logical and effective approach at this time, in light of the unavailability of human tumor-specific markers.—JNCI 1982; 68:99–105.

Assay of acid phosphatase activity (EC 3.1.3.2) has been used as an aid in the diagnosis of prostate cancer, since Gutman et al. (*1*) in 1936 reported an association between elevated serum acid phosphatase and metastatic prostate cancer. Recently, several immunochemical procedures have been developed for quantitation of serum PAP (*2–8*). By these immunoassays with antisera specific to PAP, various results with regard to the detection of elevated serum PAP in prostate cancer have been reported.

This laboratory reported 2 years ago the identification and purification of a new antigen, PA (*9*). By an immunocytochemical technique, PA has been shown to be localized in the cytoplasm of prostatic ductal cells (*10*). Human prostate tumor cells in vitro and in vivo also express this antigen (*11*). Circulating PA in patients with prostate cancer has been shown to be biochemically similar and immunologically identical to that of prostate tissue (*12*). Further, a sensitive sandwich-type ELISA has been developed for quantitation of PA (*13*). PA was not detectable in sera from healthy females or from female cancer patients. Sera from male patients with cancers other than prostate cancer contained a range of PA similar to that of healthy males. However, patients with prostate cancer had significantly elevated levels of serum PA. Since PA is biochemically and immunologically distinct from PAP (*9, 11*), the expressions of these two prostate-specific proteins may be unique parameters in combination tests for serologic detection of prostate cancer. The data may provide useful information for the design of multiple marker studies for cancer. Also, new potential uses of tissue- or organ-specific antigens, rather than tumor-specific antigens, may be realized in the immunodiagnosis of cancer. This report describes our initial evaluation on the simultaneous measurements by two ELISA procedures of serum PA and PAP in prostate cancer.

MATERIALS AND METHODS

Materials.—HRP (EC 1.11.1.7: type VI, RZ3.2, lot #59C-9760), 2,4-dinitrofluorobenzene, sodium borohydride, *o*-dianisidine, poly-L-lysine succinate, and BSA were purchased from Sigma Chemical Co., St. Louis, Mo. Sodium metaperiodate and monoethanolamine were obtained from Fisher Scientific Co., Fair Lawn, N.J. Sephadex G-200 was the product of Pharmacia Fine Chemicals, Piscataway, N.J.

Normal human sera were collected from apparently healthy volunteers 24-65 years old. Serum specimens from patients with histologically confirmed prostate cancers and BPH were received from the National Prostatic Cancer Project's Serum Bank and Gifu University School of Medicine, respectively. Prostate cancers were staged by investigators of the National Prostatic Cancer Project (*14*). All patients had active disease, although some patients were receiving treatment. Most patients with stages A, B, and C cancer had had no treatment. All patients with advanced stage D were refractory to hormone or radiation therapy and had not yet been given chemotherapy. Sera from patients with other cancers were obtained from Roswell Park Memorial Institute; all of these patients had metastatic cancer. Specimens were stored at −85°C until used.

Immunologic reagents.— Preparation of purified PA and PAP and production of specific anti-PA and anti-PAP antisera in the goat were reported previously (*3, 6, 9, 12*). The IgG fraction of goat immune sera was prepared by ammonium sulfate precipitation and Sephadex G-200 gel filtration (*13*). The IgG fraction from goat normal serum was isolated in the same manner. Coupling of HRP to anti-PA IgG and anti-PAP IgG was described previously (*13*).

Coating of anti-PAP to tube.—Coating of anti-PAP IgG to a polystyrene tube (12×75 mm) was done by the procedure of Kelsoe and Weller (*15*). Each tube was incubated first with 200 µl of solution containing 0.25 mg of poly-L-lysine succinate/ml for 15 minutes at room temperature. The tube was washed three times with 1 ml of PBS, after which 200 µl of anti-PAP IgG or normal goat IgG in 0.01 *M* carbonate buffer (pH 9.6; 50 µg/ml or 25 µg/ml) was added to each tube and each tube was incubated at 37°C for 24 hours. Then 1 ml of 1% BSA in PBS was added to the tube to saturate any uncoated sites. After 3 hours of incubation at 37°C, the antibody-coated tube was stored at 4°C until used.

Quantitation of PAP.—Purified PAP or a diluted serum sample (200 µl) was incubated in an anti-PAP-coated tube for 3 hours at 37°C. To each tube was added 1 ml of washing buffer (PBS containing 1% BSA and 0.01 *M* EDTA:Na salt). After gently whirling in a vortex, 1 ml of the solution was removed. This washing step was repeated three times. HRP-labeled anti-PAP IgG (100 µl) was then added, and the tube was incubated for another 3 hours at 37°C, which resulted in the formation of anti-PAP IgG:PAP:anti-PAP IgG-HRP. After the tube was washed three times, the peroxidase activity of the complex was then quantitated as described previously at 403 nm (A_{403}) (*13*). The percentage bound was calculated from $[(B-Bo)/(B_t-Bo)]\times100$, where $B=A_{403}$ of the sample, $B_t=A_{403}$ of maximum, and $Bo=A_{403}$ of the blank. Each assay was performed in duplicate with two controls, one blank (without sample) and the other containing purified PAP at a concentration of 10 µg/ml for the maximal binding. The quantity of PAP in the specimen was determined from a standard curve constructed in an identical manner with the use of various concentrations of purified PAP.

The reproducibility of this procedure was evaluated by the determination of the coefficients of variation between assays (i.e., two samples containing different concentrations of PAP were assayed in 10 separate experiments) and by the determination of the variation within assays (i.e., two other samples with different PAP levels were analyzed in a series of 10 assays each) (*13*).

Nonspecific adsorption of the tube-coated anti-PAP IgG.—A total of 27 normal male sera were tested for nonspecific adsorption to the insolubilized antibody with the use of goat normal IgG coated to the tube.

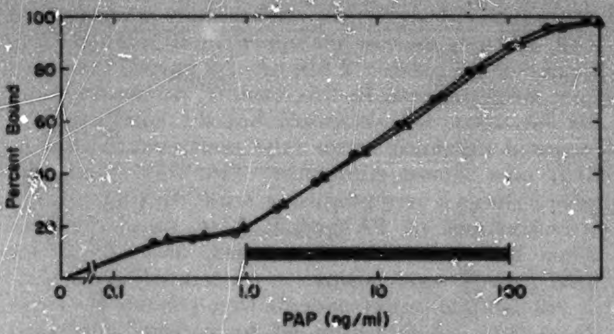
Quantitation of PA.—Serum PA levels were determined by the ELISA procedure as reported recently (*13*); by this procedure, anti-PA IgG was conjugated to a solid-phase support, CNBr-activated Sepharose 4B. After incubation of the specimen with Sepharose 4B-anti-PA, the resulting Sepharose-anti-PA:PA was further reacted with anti-PA-HRP. The HRP in the sandwich-type Sepharose 4B-anti-PA:PA:anti-PA-HRP was then quantitated and used as a parameter for serum PA concentration.

RESULTS

ELISA of PAP

The newly developed, tube-supported, sandwich-type ELISA of PAP, as performed by the experimental protocol described, yielded a working range of 1.0-100 ng of PAP/ml of serum sample (text-fig. 1). Quality-control data of within-assay variation (two levels of PAP, 6.5 and 35, and 10 assays each) and between-assay variation (two levels of PAP, 2.6 and 51, and 10 assays each) revealed an overall mean coefficient of variation of 4.3% (ranging from 3.2 to 5.7%), indicating that this new enzyme immunoassay for PAP was a reproducible procedure. With the use of a tube coated with goat preimmune IgG, rather than with goat immune anti-PAP IgG, 27 serum specimens of healthy males were shown to have levels of nonspecific binding from 15 to 19% (mean, 17.4%). The ranges represented approximate values of 1.0 ng or less, the sensitivity limit of this ELISA (text-fig. 1). Therefore, the PAP assay was performed without the simultaneous use of a control, e.g., a preimmune goat IgG-coated tube.

In addition, sera from a group of 27 apparently



TEXT-FIGURE 1.—Standard calibration curve of PAP as determined by the ELISA with the use of a hundredfold-diluted HRP-anti-PAP IgG and 10 μg of anti-PAP IgG applied to a polystyrene tube. ●, purified PAP; ▲, serum containing 480 ng PAP/ml as standard. *Horizontal bar* indicates the working range of this ELISA. Percent bound was calculated by the formula $[(B-Bo)/(B_t-Bo)]\times 100$, where $B = A_{405}$ of the sample, $B_t = A_{405}$ of the maximum, and $Bo = A_{405}$ of the blank as indicated in the text.

healthy normal male controls were shown by this ELISA to have PAP levels ranging from less than 1.0 to 13 ng/ml with a mean plus or minus standard deviation of 4.4±3.7. For statistical analysis, an upper cutoff point for the normal range was, therefore, calculated as 15.5 ng PAP/ml of serum (mean + 3 SD).

Single Assay of PAP

Serum PAP values in patients with prostate cancers, BPH, and other cancers are shown in table 1. Thirty male patients with cancers of the lung, pancreas, and colon-rectum (10 each) showed a range of serum PAP similar to that seen in 27 healthy males, as did 29 patients with BPH. A significantly higher mean serum PAP value, however, was obtained from patients with all clinical stages of prostate cancers. The mean of serum PAP in 12 patients with stage A prostate cancer, 15.5 ng/ml, was equal to the upper cutoff point for the range in 27 healthy males. In addition, the mean serum PAP increased with increasing disease stage. Serum PAP levels were elevated in 33% of stage A, 42% of stage B, 64% of stage C, and 73% of stage D prostate cancer patients. Text-figure 2 shows a scattergram of the data presented in table 1 for males.

This study also included serum "PAP" values from 10 healthy female controls and 19 female cancer patients. As table 1 shows, all mean values were less than 1.5, representing circulating acid phosphatase of nonprostate origin or other proteins that may react nonspecifically with goat anti-PAP serum by the ELISA procedure, although anti-PAP serum used in the assay previously has been shown by immunoprecipitation and immunocytochemical techniques to be specific to acid phosphatase of prostate origin.

Single Assay of PA

The PA assay also was performed in serum specimens at the time that PAP levels were determined. For statistical analysis, an upper cutoff value also was calculated from the means + 3 SD of healthy controls, which yielded a value of 2.5 ng PA/ml of serum. As reported previously, the sensitivity of our ELISA of PA was 0.10 ng/ml, and sera of all females, either healthy controls or cancer patients, contained PA less than 0.10 ng/ml (as further demonstrated in the 29 specimens assayed in this study). Again, with one exception, male patients with cancers other than prostate cancer had serum PA values of less than 2.5 ng/ml. Although 41% (12/29) of the BPH patients exhibited elevated serum PA levels, more prostate cancer patients [67% (8/12) with stage A cancer, 69% (25/36) with stage B, 79% (22/28) with stage C, and 83% (96/116) with stage D] demonstrated an elevated PA with a higher mean value

TEXT-FIGURE 2.—Serum PAP levels in healthy male controls (Normal Male), male patients with cancers other than prostate cancer (Non-pr. Cancer), patients with BPH, and patients with prostate cancers of various stages. *Broken horizontal line* shows a PAP level of 15.5 ng/ml, the upper limit of the normal range (mean + 3 SD).

(text-fig. 3). In comparison to the PAP assay, the PA assay registered positive values more often in the BPH patients.

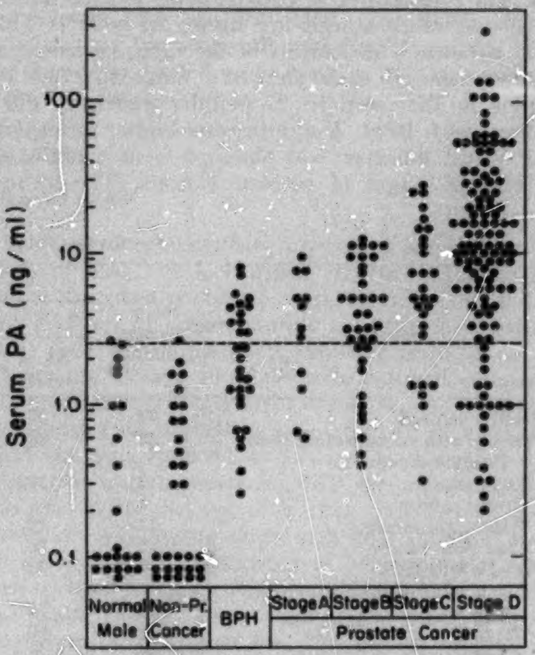
Multiple Assays of PA and PAP

Among 22 healthy male controls, 29 BPH patients, 192 prostate cancer patients, and 30 males with other cancers, assays of both PA and PAP were performed simultaneously. The elevation of either PA or PAP levels was then determined. Overall, 64 and 79% of 192 patients with prostate cancers had elevated PAP and PA levels, respectively. As already noted, an elevated PA also was shown in a higher percentage of the patient population. It was found in 67% of the patients with stage A prostate cancer, 69% with stage B, 79% with stage C, 83% with stage D, and in 41% of the patients with BPH. In comparison with the elevations in PA levels, the levels of PAP were elevated in 34, 41, 64, and 74% of the patients with stages A, B, C, and D prostate cancers, respectively, and in 7% of the patients with BPH. For both assays, 83% of the patients with stage A cancer to 94% of the patients with stage D were shown to have elevated PA and/or PAP values, although 48% of the patients with BPH also registered as positive in either PA or PAP assay.

In practice, for multiple marker study using PA and PAP, one may increase the upper cutoff point of PA to a value of the mean + 2 SD, i.e., 7.5 ng/ml, calculated from BPH patients. In this manner, the sensitivity of the PA assay was decreased, but the specificity was increased inasmuch as the false positives presented by BPH were almost eliminated. With this adjustment, table 2 shows a very promising result for simultaneous determinations of PA and PAP in prostate cancer. When both assays were combined, only 10% of the BPH patients were positive in the test. Also, 153 (79%) of 192 prostate cancer patients were positive for either PA or PAP, ranging from 58% for patients with stages A and B each, to 68% for patients with stage C, to 92% for patients with stage D; a significant number (53) of the patients were positive with both assays. Furthermore, patients with other cancers or healthy controls registered no positive assay. Therefore, these results as derived from two prostate tissue antigens that were measured simultaneously clearly demonstrated an additive value.

DISCUSSION

Data obtained from simultaneous assays of two prostate-specific markers, PA and PAP, have been presented. Serum PA is quantitated by an established solid-phase sandwich-type (Sepharose 4B-anti-PA:PA: anti-PA-HRP) ELISA (*13*), whereas PAP is measured



TEXT-FIGURE 3.—Serum PA levels in healthy male controls, male patients with cancers other than prostate cancer (Non-Pr. Cancer), patients with BPH, and patients with prostate cancers of various stages. *Broken horizontal line* indicates a PA level of 2.5 ng/ml, the upper limit of the normal range (mean + 3 SD).

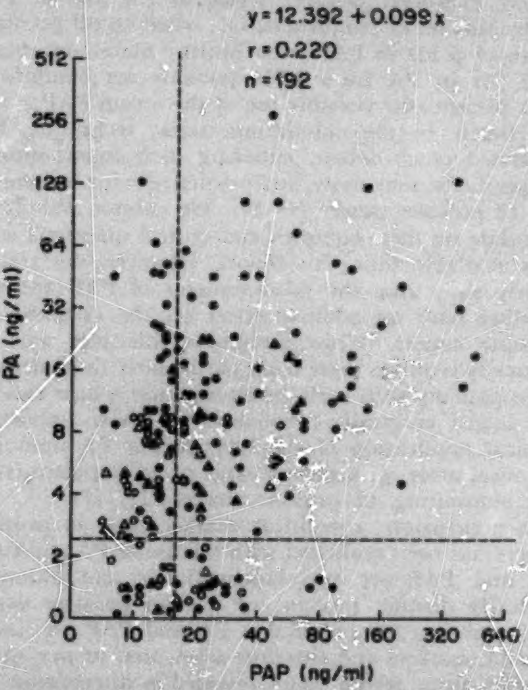
by a newly reported, tube-supported, sandwich-type (tube-anti-PAP:PAP:anti-PAP-HRP) ELISA. The ELISA of PAP detects an antigenic protein of the enzyme, unlike our several other immunochemical procedures, such as counterimmunoelectrophoresis (*3, 8*), fluorescent immunoassay (*4*), immunoadsorbent assay (*6*), and the double-antibody immunoenzyme assay of Choe et al. (*5*), which detect both antigenic sites and the hydrolytic activity of the enzyme. In this ELISA of PAP, the HRP activity of the final conjugate, tube-anti-PAP:PAP:anti-PAP-HRP, is measured and serves as an index for quantitation of PAP. This assay detects more elevated serum PAP in the early stage of prostate cancer than does the counterimmunoelectrophoresis technique (*3, 8*) but reveals a similar detection rate as the fluorescent immunoassay (*4*) or the immunoadsorbent assay (*6*).

Both PA and PAP are proteins of human prostate-specific origin (*3, 9*). Biochemically, PA is a glycoprotein of molecular weight 33,000 with a pI of 6.9, whereas PAP is a larger, 100,000, glycoprotein with multiple pI ranging from 4.2 to 5.5 (*3, 9, 16*). Immunologically, PA and PAP are two distinct antigen moieties; i.e., antisera possess specific reactivity against their respective antigens and demonstrate no cross-reactivity with each other (*12*). PA is not a subunit or a related peptide of PAP, because both proteins exhibit different amino acid compositions and peptide mapping (*17*). As text-figure 4 shows, different levels of PA and PAP are expressed by patients with prostate cancer; i.e., in some patients PAP levels are in the normal range, while PA levels are elevated. Further, although not prostate tumor-specific, PA and PAP have been shown to be promising markers in the detection of prostate cancer; they may reflect different aspects of neoplastic transformation in prostate cancer. These observations are the rationale for this study.

In evaluating the possible role of serum PA and PAP assays in the immunodiagnosis of prostate cancer, we have used the conventional mean + 3 SD of male controls as the upper normal limits for serum PA and PAP values. Under these criteria, each assay alone detected an elevation of PAP and PA in 64 and 79% of prostate cancer patients, respectively. None of the healthy males and 7% of the BPH patients had an elevated PAP, whereas 9% of the healthy males, 3% of the patients with cancers other than prostate cancer, and 41% of the BPH patients demonstrated an elevated PA value. In the combination test, these individuals also registered positive assay values. However, in pros-



TEXT-FIGURE 4.—Simultaneous assays of serum PA and PAP in 192 randomly selected prostate cancer patients. *Two broken lines* indicate the upper normal limits of serum PA and PAP. △, stage A; ○, stage B; ▲, stage C; ●, stage D. y, PA; x, PAP. r=correlation coefficient; n=number.

tate cancer, a combination of these two assays increased the positive detection rate of PA and/or PAP to 83% for the patients with stage A prostate cancer, 89% for the patients with stages B and C, and 94% for the patients with stage D. The PA assay alone and the PAP assay alone gave respective rates of 57, 69, 79, and 80% and 33, 42, 64, and 73% for patients with stages A, B, C, and D prostate cancers. An elevated PA level still was detected in 41% of the BPH patients as indicated.

As already indicated, one advantage of a combination test with the use of prostate-specific markers is the increase in the sensitivity of detection of an elevation of either marker in prostate cancer. It is of concern that 41% of the BPH patients exhibited an elevated PA. Another obvious advantage in the use of a combination test is that adjustment can be made of various cutoff points for each marker assay and comparisons can be done of the sensitivity and specificity of the combined test. In this study, the cutoff of PA is calculated as the level of the mean + 2 SD for BPH, 7.5 ng/ml, and used for analysis of combined PA and PAP assays. Comparison of the sensitivity and specificity of the combination test results in an impressive figure, as shown in table 2; 58% each of the patients with stages A and B prostate cancers, 68% of the patients with stage C, and 92% of the patients with stage D prostate cancers (overall, 80%) and only 10% of the patients with BPH demonstrated positive PA and/or PAP levels. In addition, no healthy control or patients with cancers other than prostate cancer exhibited positive levels of PA and/or PAP under this set of parameters, i.e., when cutoff points of means + 3 SD in PAP from healthy males and means + 2 SD in PA from BPH patients are combined.

At present, the possible use of the serum PAP assay, specifically by the radioimmunoassay technique, has generated much debate, entailing such considerations as specificity, sensitivity, and predictive value for screening of prostate cancer (*18-20*). We cannot address or speculate on these complex and critical questions with data available from this report. However, our results clearly show that the measurements of PAP and PA together have an additive effect on the diagnosis of prostate cancer. What usefulness this fact will be clinically requires more data, particularly those derived from patients with early prostate cancer whose cancers are staged surgically. Probably, the most important clinical application of the PAP and/or PA immunochemical assay at its present stage of development is for the monitoring of prostate cancer (*21, 22*).

In conclusion, a multiple marker assay in prostate cancer has been evaluated with the use of PA and PAP. PA and PAP are two biochemically and immunologically distinct proteins of human prostate tissue. Although not tumor-specific, PA and PAP are tissue-specific markers and therefore were used in our study. Results from serum assay revealed a discordance between the PA and PAP values, which thus suggested that the expressions of these two markers reflect different aspects of the biology of prostate cancer. Combination tests with different and selected values of PA and PAP levels produced very encouraging results. This study demonstrates that a combination test of tissue-specific markers can result in additive clinical value in the immunodiagnosis of cancer and should be a logical avenue for serious consideration at this time in light of the absence of human tumor-specific markers.

Environmental Factors in the Etiology of Rhabdomyosarcoma in Childhood[1,2,3]

ABSTRACT—In a case-control study of childhood rhabdomyosarcoma (RMS), families of 33 cases and 99 controls were interviewed. A relative risk (RR) of 3.9 was found associated with fathers' (but not mothers') cigarette smoking ($P=0.003$). Cases had had fewer immunizations than controls, particularly smallpox vaccination (RR=0.2; $P=0.001$), and conversely had more preventable infections. An RR of 3.2 ($P=0.03$) was found associated with exposure to chemicals and an RR of 3.7 ($P=0.004$) was found associated with diets that included organ meats. Mothers of cases were more likely to be over age 30 years at subject's birth, to have used antibiotics preceding or during pregnancy, and to have had an overdue and/or assisted delivery. Other findings suggest that low socioeconomic status is associated with an increased risk of RMS. These aggregate findings imply that environmental factors may play an important role in the etiology of childhood RMS.—JNCI 1982; 68:107–113.

RMS is the sixth most common cancer of childhood with an annual incidence of about 4 cases per million children (*1, 2*). Little is known about its epidemiologic features, and there are few etiologic hypotheses for this rare disease. Previous epidemiologic studies, based on mortality statistics and case series, indicate the following: Males are more susceptible than females, with whites being more susceptible than blacks; the peak incidence is at about ages 3–4 years; relatives of patients are at markedly increased risk of RMS; and there appears to be familial aggregation of RMS with other soft tissue sarcomas and breast cancer (*3–5*). In this first case-control study of childhood RMS we evaluated possible etiologic factors.

SUBJECTS AND METHODS

We attempted to identify all incident cases of childhood RMS in NC residents during the period 1967–76. Diagnostic indexes, tumor registries, and pathology logs were searched at 141 of the 150 nonpsychiatric hospitals in NC that admit children and at three major referral hospitals in two adjacent states. The nine nonparticipating institutions were military hospitals, which usually referred their pediatric oncology patients to in-state civilian hospitals for care. A total of 37 cases was identified, and the subjects were 0–14 years of age; all but 1 were diagnosed at an NC hospital. We also searched the NC State Tumor Registry and oncology records at the (then) three NC medical schools but found no additional cases. To be eligible for study, a patient ("case") had to have been born in NC and reside there at the time of a histopathologically confirmed diagnosis. Because birth certificates served as our means of selecting controls, cases also had to have a birth certificate on file with the NC Department of Human Resources. Four of the 37 cases were excluded: Two had been born out of state; 1 had been adopted (hence her birth certificate was not publicly listed), and another, although born in NC, had no birth certificate on file. For each of the 33 resulting cases, 3 controls of the same age (±2 mo), sex, and race were randomly selected from NC birth certificates. We excluded subjects who had been adopted, who had died during the neonatal period, or who had been born to parents serving in the military.

Recent addresses for case families were obtained in most instances from their physicians and from medical records. Current addresses for the parents of controls were obtained by a variety of means. The first resource was a library of telephone and city directories from which we tried to match an address with that on the birth certificate. Where necessary, we next searched driver's license and motor vehicle registries. In some instances it was possible to trace parents through the physician listed on the birth certificate. Our last resort was to visit the town of last known address and make inquiries of neighbors and at the post office.

Abbreviations used: NC=North Carolina; RMS=rhabdomyosarcoma; RR=relative risk(s); SES=socioeconomic status.

[10] We thank the hospitals of North Carolina for their generous assistance; the Vital Records Branch of the North Carolina Department of Human Resources for providing us with controls; and Ms. M. Griffin, Ms. J. McMillan, Ms. J. Wood, and Ms. K. Baker for their long hours on North Carolina's highways and byways to interview our subjects.

We were thus able to trace all 33 cases. Of the 99 controls first selected, only 70 were found and interviewed; 9 were located but refused to participate, and the other 20 were untraceable. These 29 controls were then replaced by children whose birth certificates were selected by the same methods described above. Twenty-three of these replacements were located and interviewed; 1 more was located but refused to participate, and the other 5 could not be found. A second replacement was chosen for these 6 controls by the same methods. Five of the 6 second-round replacements were interviewed, and 1 refused to cooperate. This control was replaced by a third-round selection.

Using the information on birth certificates, we assessed bias potentially introduced by our loss and replacement of original controls. First, we compared the participating original (first-round) controls with all of the lost and nonparticipating ones and found similar distributions of sex, race, date of birth, extent of parents' education, parents' age at birth of subject, region of residence, duration of pregnancy, and father's occupation (table 1). This finding indicates that the lost and nonparticipating controls were quite similar to the participating first-round controls. Second, we compared the lost and nonparticipating controls with their replacements. As shown in table 1, the only major difference between these 2 groups was in the area of father's occupation. Fewer replacement controls had fathers with professional or managerial occupations, and replacements had more prenatal visits.

Since our evaluation of potential bias was based on birth certificate information, we assessed the reliability of this information by checking it against our interview data. The correlation between fathers' occupations (in terms of "professional and managerial" vs. "other") from the two sources was 0.83. Similarly, the correlation coefficient for years of fathers' education was 0.58 and for years of mothers' education, 0.68.

After case and control families had been located, they were invited by letter to participate in a "study of child health." Interviews were then arranged by telephone call or home visit if the family had no telephone. A standard questionnaire was administered by trained interviewers. The mean duration of interviews for cases was 70.5 minutes and that for controls, 65.1 minutes. All but eight interviews were conducted in the subjects' homes. Three took place at the mothers' place of employment (1 case and 2 control mothers) and one at Duke University Medical Center (a case); four were done by telephone because the families had moved out of NC (2 cases and 2 controls). The informant in all but two instances was the subject's parent, usually the mother (91% of cases and 92% of controls).

In our analyses, we estimated RR and 95% confidence intervals by using both matched and unmatched methods (*6–8*). Since results from both analyses were similar (the differences being <10%), only the unmatched results are presented. Since the purpose of our study was to generate hypotheses for later confirmation, we made no effort to adjust for the multiple testing situation in which we examined numerous potential risk factors. Even if none of the factors examined were related to risk of RMS, an analysis such as this would be expected to generate *P*-values of less than 0.05 for 5 of every 100 variables. Thus for those variables that we have found to be significant, the actual significance level may be greater than our stated *P*-value.

RESULTS

SES.—The first group of variables examined were correlates of SES (table 2). We found the estimated RR associated with mothers' education beyond high school to be 0.3 ($P=0.04$); that for fathers was 0.5 ($P=0.13$). Similarly, the RR associated with mothers' having professional or managerial occupations was 0.4 and that for fathers was 0.5. The RR associated with annual family income of $10,000 or more was 0.5 ($P=0.09$). Whereas only one of these variables reached statistical significance at the 0.05 level, all RR were markedly low and deviated in the same direction from unity. This confluence of findings suggests that low SES is a risk marker for RMS.

Family medical history.—A second group of ques-

TABLE 1.—*Comparison of birth certificate information: Participating, lost and nonparticipating, and replacement controls*

Birth certificate information	Participating original controls[a]	Lost and non-participating controls[b]	Replacement controls[c]
Percentage of fathers with professional or managerial occupations	28	27	11
Mean years of fathers' education	11.6	10.5	12.0
Mean years of mothers' education	11.5	11.7	11.2
Mean age of fathers at subjects' birth	26.6	28.1	28.2
Mean age of mothers at subjects' birth	24.1	25.0	25.4
Percentage of married mothers	100	100	100
Percentage of mothers attended by physician at delivery	96	96	100
Mean gestational period, wk	38.5	38.4	39.1
Mean No. of prenatal visits	10.1	8.7	10.3

[a] No. = 70.

[b] No. = 36

[c] No. = 29.

TABLE 2.—*Childhood RMS risk factors: Socioeconomic indicators*

Risk factors	No. of cases (%)	No. of controls (%)	RR	95% confidence interval
Mothers with ≥13 yr of education	4 (13)	31 (32)	0.3	0.1–0.9
Fathers with ≥13 yr of education	6 (19)	31 (33)	0.5	0.2–1.3
Mothers with professional or managerial occupations	3 (14)	18 (29)	0.4	0.1–1.6
Fathers with professional or managerial occupations	6 (21)	29 (34)	0.5	0.2–1.5
No. of families with annual income of $10,000 or more	14 (44)	59 (61)	0.5	0.2–1.1

tions dealt with family history of disease (table 3). The estimated RR for cancer in relatives of cases versus controls was 2.3 ($P=0.08$). However, when restricted to first-degree relatives—where recall would be more complete for both cases and controls—there was little difference in history of cancer between case and control families (RR=0.7). Thus there was probably "selective recall" bias wherein case families are more apt to remember cancer in remote relatives.

We found an association of RMS with family history of asthma or allergies (RR=2.5; $P=0.03$). When we restricted this analysis to first-degree relatives only, we found little change. Thus this finding is probably not subject to selective recall. Despite the more frequent history of asthma and allergies in case families, the RR for relatives' having received "allergy shots" was 0.4; however, this finding was not close to being statistically significant. Perhaps related to the asthma and allergies finding was our finding of an RR of 1.9 associated with a family history of frequent or serious infections. We also found an association with family history of anemia (RR=2.1).

Gestational and delivery factors.—Several gestational and perinatal factors appeared to be associated with RMS (table 4). Mothers' use of antibiotics within 1 year preceding or during the subjects' gestation conferred an RR of 2.7 ($P=0.03$). Additionally, the RR associated with mothers' being over 30 years of age at the time of delivery was 2.6 ($P=0.06$). The RR associated with overdue versus normal delivery was 2.8 ($P=0.03$); that associated with premature delivery was 0.6. Forceps or cesarean section delivery conferred an RR of 2.4 ($P=0.10$). Thus the age of the mother, the length of her pregnancy, "assisted delivery," and gestational use of antibiotics may be risk markers for RMS. The RR for radiographic examination during pregnancy in case mothers versus control mothers was 0.5.

Neonatal history.—The RR associated with a history of neonatal jaundice was 0.3; that associated with neonatal conditions requiring medical treatment was 0.4 (table 5). However, the occurrence of neonatal problems was infrequent in cases and controls and none of the associations in this category was statistically significant at the 0.05 level.

Environmental exposures.—We also examined several environmental exposures (table 6). We found an RR of 3.2 associated with exposure to chemicals other than pesticides and rodenticides. This category includes exposures to such substances as solvents, paints, acids, bleaches, fertilizers, and gasoline. The only substances to which more than 1 case was exposed were chemical fertilizers. Three cases (9%) and 1 control (1%) had been exposed to fertilizers, yielding an RR of 10.0 (1.5–68, 95% confidence interval). Some of the cases had more than one type of chemical exposure. Similarly, living near a factory that emitted chemical pollution conferred an RR of 3.3 ($P=0.24$).

Diet.—The estimate of RR associated with the eating of organ meats (e.g., liver, brain, and tongue) was 3.7 ($P=0.004$) (table 7). Case families also used less animal fat (lard) in cooking than did control families (RR=0.4). No other dietary factors appeared remarkably associated.

Immunization history.—Cases had received far fewer routine childhood immunizations than had controls (table 8). The RR for smallpox vaccination was 0.2 ($P=0.001$), for measles-mumps-rubella immunization 0.3, and for diphtheria-pertussis-tetanus immunization 0.7. We assessed the RR associated with overall immunization status in terms of "any immunizations" versus "no immunizations" and obtained an estimate of 0.7. We did not include the estimate of RR for poliomyelitis immunization because one of the cells in the related fourfold table contained a zero value. All 33 cases and 96 of 98 controls had received this immunization (RR=0). In general, the RR deviated most from unity for those immunizations that might have a greater discretionary component on the part of the family (i.e., immunizations given latest in infancy).

Past medical history.—We found an RR of 4.1 (exact

TABLE 3.—*Childhood RMS risk factors: Family medical history*

Family history of	No. of cases (%)	No. of controls (%)	RR	95% confidence interval

P=0.05) associated with prior history of whooping cough and of 4.3 for impetigo (exact *P*=0.07) (table 8). There was also an increased history of measles (RR=2.0) and of asthma (RR=2.3) in cases. However, there was no association between RMS and history of infectious diseases for which no immunizations are available, such as otitis media or chickenpox (RR=0.9 for both). The RR associated with scarlet fever was 0.5.

Miscellaneous factors.—Table 9 summarizes our evaluation of a number of miscellaneous potential risk factors. Fathers who were ever-smokers (relative to those who were never-smokers) conferred an RR of 3.9 (*P*=0.003). This finding was in contrast to the findings of an RR of 0.8 for children of mothers who were ever-smokers and of 1.0 for children of mothers who smoked cigarettes during their pregnancy.

TABLE 6.—*Childhood RMS risk factors: Childhood environment*

Family consumption of meats:				
Beef (>2 vs. ≤2 times/wk)	16 (50)	53 (54)	0.9	0.4–1.9
Pork (>2 vs. ≤2 times/wk)	9 (28)	19 (20)	1.6	0.6–4.0
Chicken (>2 vs. ≤2 times/wk)	7 (22)	17 (17)	1.4	0.5–3.6
Fish (>2 vs. ≤2 times/wk)	4 (13)	16 (16)	0.7	0.2–2.4

Assessment of confounding by SES.—Because we were concerned that some of our findings might be confounded by SES, we controlled for family income and fathers' education and occupation in a matched logistic regression analysis of fathers' cigarette smoking and of smallpox vaccination status. In the analysis of fathers' smoking, we obtained an adjusted RR of 2.8 ($P=0.07$). In the analysis of smallpox vaccination, we obtained an adjusted RR of 0.2 ($P=0.009$). Due to incomplete data, the number of subjects included in these analyses was smaller than that in the univariate analyses.

TABLE 8.—*Childhood RMS risk factors: Subject's medical history*

Risk factors	No. of cases (%)	No. of controls (%)	RR	95% confidence interval
Smallpox vaccination	21 (66)	88 (90)	0.2	0.1–0.6

Asthma	3 (9)	4 (4)	2.3	0.5–11

DISCUSSION

This study uncovered a number of potential risk factors for RMS. First, we found a confluence of associations with variables related to SES. We found that both mothers and fathers of cases had received less education than control parents, that case parents' occupations tended to be of a lower income and prestige level, and that total family income for cases was lower than that for controls. Whereas only mothers'

TABLE 9.—*Childhood RMS risk factors: Miscellaneous factors*

Risk factors[a]	No. of cases (%)	No. of controls (%)	RR	95% confidence interval
Fathers who smoke cigarettes (ever)	23 (77)	40 (46)	3.9	1.5–9.6
Mothers who smoke cigarettes (ever)	8 (26)	29 (31)	0.8	0.3–2.0
Religion (Protestant vs. other)	26 (81)	68 (81)	1.0	0.4–2.9
Birth order (first vs. other)	13 (39)	41 (41)	0.9	0.4–2.1
No. of children in sibship (>5 vs. ≤5)	7 (21)	14 (14)	1.6	0.6–4.5
Father's age at subject's birth (>30 vs. ≤30 yr)	7 (22)	25 (26)	0.8	0.3–2.0
Marital status of mother (married vs. other)	23 (70)	73 (75)	0.8	0.3–1.8

Farm residence (ever vs. never)	2 (6)	6 (6)	1.0	0.2–5.2
Current residence (outside an SMSA vs. in an SMSA)	23 (70)	62 (64)	1.3	0.6–3.0

[a] SMSA = standard metropolitan statistical area.

educational level showed a statistically significant association with RMS and family income was at the margin of statistical significance, all of these factors, in the aggregate, suggested that low SES is a risk marker for RMS. Our characterization of lost and nonparticipating controls and comparisons with participating controls suggested that if our selection and location procedures introduced any SES bias, it was of a conservative nature.

Other studies that examined childhood cancer risk in relation to social class have dealt primarily with leukemia. Stewart et al. (*9*) found no association between social class (as indexed by father's occupation alone) and the risk of leukemia or of all childhood cancers. Fasal and co-workers (*10*), using birth and death certificates of children who died of leukemia, found a small but statistically significant increase in leukemia risk for children of high social class ($RR=1.33$; $\chi^2_1=4.58$), with social class defined by fathers' occupation. Although prior studies have found no or weak associations between social class and childhood cancer risk, these studies have been limited by having minimal data available for the classification of families' social class.

Perhaps our most salient finding is the strong association between RMS and fathers' cigarette smoking. This finding has two possible explanations. First, a direct carcinogenic effect may be introduced either in a prezygotic manner or by passive inhalation of cigarette smoke by the patients. In support of a direct effect are two studies suggesting a mutagenic effect of fathers' cigarette smoking. Evans and co-workers (*11*) found morphologic sperm abnormalities in cigarette smokers, and Mau and Netter (*12*) showed a twofold increase in the occurrence of severe malformations in children of fathers who were heavy cigarette smokers. The second interpretation relates to SES. Wynder and Hoffmann (*13*) showed that cigarette smoking is inversely related to educational level among men but not among women. Thus the positive finding for fathers but not for mothers may relate to our observation that low SES may be a marker of increased RMS risk. However, the results of our matched logistic regression analysis suggest that this is not a likely explanation. We believe the first hypothesis deserves further consideration.

Most of the numerous studies of mothers' cigarette smoking and risk of malformation in their offspring have shown no or weakly positive associations. The U.S. Surgeon General's 1979 Report on Smoking and Health (*14*) concluded: "There is no convincing evidence that maternal smoking increases the incidence of congenital malformations. Results of published studies, reviewed in the 1973 report (*15*), show relative risks for smokers versus nonsmokers ranging from 0.31 to 1.55." Thus if Mau and Netter's findings (*12*) prove valid, our observation of a possible association between fathers' (but not mothers') cigarette smoking and risk of RMS appears even more worthy of further study.

Several studies have directly examined cancer risk of children in relation to their parents' smoking status (*9, 16–18*). All have shown little or no association between mothers' smoking and cancer risk in their offspring and therefore are consistent with our findings. We found only one study that evaluated the association between fathers' smoking and risk of cancer among their children. Stewart et al. (*9*) found that fathers of children with leukemia were only slightly more apt to be smokers than those of control children, but the authors point out that their analysis was crude.

We found internal consistency in our study when we examined immunization status and history of infectious diseases. Cases had received remarkably fewer immunizations than had controls and, conversely, they had contracted more of those diseases preventable by immunization. The association of RMS with impetigo, a disease associated with poor hygiene, was also interesting. Our finding of an association with history of pertussis is similar to an observation made by Bross and Natarajan (*19*) in a study of children with leukemia. These investigators found a twofold increase in leukemia risk for children with a history of antecedent bacterial infection (defined as "pneumonia, whooping cough, or dysentery").

Our findings of fewer immunizations in cases are similar to those in Neumann's study (*20*) of children dying of cancer in Baden-Württemberg, Federal Republic of Germany. Neumann found statistically significantly less diphtheria immunization in case children than matched controls ($RR=0.25$). His cases had less tetanus ($RR=0.46$), poliomyelitis ($RR=0.75$), and BCG ($RR=0.69$) immunizations but more smallpox vaccination ($RR=1.28$) than did his controls, though these differences were not statistically significant. All of his findings are consistent with ours except for those with regard to smallpox vaccination. This would suggest that the specific immunizations are not themselves risk factors, but that immunization status per se is a risk marker for childhood cases.

We found a notable association with exposure to chemicals and chemical pollution. Cases also appeared to have eaten more organ meats than did controls and somewhat more pork ($RR=1.6$). The increased consumption of organ meat and pork may be interrelated in that NC farmers (and rural families) who slaughter their own pigs will usually utilize all organ and "variety" meats.

We found associations between RMS and several gestational and parturitional factors. These include a positive association with an overdue delivery and, conversely, a negative association with premature delivery of the propositus. Additionally, use of forceps and cesarean section in the delivery of subjects and use of antibiotics by mothers during the year and 9 months preceding the birth of their children appear to be risk markers of RMS. We found an interesting association with mothers' age at birth of subjects. Similar observations were made in earlier studies, which showed that mothers of children with leukemia were significantly older than mothers of controls (*9, 16, 21*). One of these studies (*9*) showed that the increased risk of leukemia with increasing maternal age was independent of the occurrence of Down's syndrome. Another study showed a "consistent, although not statistically significant, trend toward increasing rates with increasing maternal age" for all childhood cancers (*21*).

The findings of an association with history of asthma and allergies in families and of an RR of 2.3 for history of asthma in subjects suggest that immunologic factors play a role in the etiology of RMS. Bross and Natarajan (*19*), in their case-control study of childhood leukemia, similarly found a threefold increase in risk associated with subjects' history of antecedent allergic diseases (asthma and hives). Manning and Carroll (*16*) showed similar results more than 20 years ago. They also found a statistically significant association between risk of childhood leukemia (and lymphoma) and mothers' history of having had allergic diseases. However, there was no increased history of allergies for children with other cancers or their mothers.

In summary, we have found a number of potential risk factors for childhood RMS. We found immunization status, fathers' cigarette smoking, diet, chemical exposures, mothers' age, gestational factors, asthma, and SES to be associated with RMS. In particular, we believe that the association with fathers' smoking is deserving of further evaluation. The aggregate of our findings implies that environmental factors may play an important role in the etiology of childhood RMS. We must, however, caution that this is the first case-control study of this rare cancer and that our study size was small. Further investigation is needed to confirm our findings in another setting.

We believe that the issue of environmental factors in the etiology of childhood cancers has not been explored adequately. The relatively short latent periods between potential etiologic exposures and disease manifestation in children provide unique opportunities for the study of environmental factors. Similar case-control studies of other childhood cancers might provide important new etiologic leads.

Anticancer Drugs: Effect on the Cloning of Raji Lymphoma Cells in Soft Agar[1]

Pao-Chen Wu,[2,3] **Robert F. Ozols,**[4,5] **Masakazu Hatanaka,**[2,6] *and* **Charles W. Boone**[2,7]

ABSTRACT—The effect of 11 anticancer drugs on the ability of Raji lymphoma cells to form colonies in soft agar was determined with the use of both a 1-hour and a continuous drug exposure. Three distinct patterns of drug sensitivities were observed: *a*) Dactinomycin, adriamycin, bleomycin, mitomycin C, vincristine, and *cis*-platinum II all produced a dose-dependent reduction in colony formation following a 1-hour exposure, which was further augmented by a continuous exposure to the drugs; *b*) the antimetabolites (methotrexate, β-cytosine arabinoside, and 5-fluorouracil) and pentamethylmelamine had no suppressive effects on colony formation with a 1-hour exposure, but they produced marked cytotoxicity with continuous drug exposure; and *c*) L-phenylalanine mustard had the same degree of colony suppression with both a 1-hour and a continuous drug exposure. Preincubation of Raji cells with an enzyme mixture (DNase + pronase + collagenase) did not alter the degree of colony suppression observed with the anticancer drugs. These results indicate that continuous drug exposure should be compared to a 1-hour drug incubation to determine in vitro drug sensitivities of fresh human tumors in the soft agar clonogenic assay, because the 1-hour drug exposure may not identify certain drugs that are potentially clinically active.—JNCI 1982; 68:115–121.

The growth of tumor colonies in soft agar from primary human tumor explants was initially described by Hamburger and Salmon (*1, 2*) and recently confirmed by other investigators (*3–5*). The human tumor clonogenic assay provides a technique to study the growth of human tumors in vitro and to determine the chemotherapeutic drug sensitivity of a particular tumor. Preliminary results indicate that the assay is 90–95% accurate in predicting clinical resistance and 60–65% accurate in predicting a clinical response (*6, 7*). Furthermore, the assay is of potential importance as a screening test for new antitumor agents (*8*). General applicability of the system has been limited in part by the lack of sufficient colony formation from most specimens to perform multiple drug sensitivities (*9, 10*).

In an effort to improve upon the mechanical disaggregation of tumors, enzymatic digestions with the use of single or multiple enzyme mixtures are under active investigation (*11, 12*). A potential concern regarding the use of proteolytic enzymes has been the possibility that these enzymes will disrupt membrane proteins of tumor cells and consequently alter the pattern of chemotherapy sensitivity. Observations regarding drug sensitivities and ways to improve the cloning efficiencies in an established human tumor cell line may have direct relevance to the soft agar cloning of fresh human tumors.

In this study we examined the effect of 11 anticancer drugs on colony formation in soft agar of Raji cells by means of both a 1-hour and a continuous exposure to various concentrations of drugs. Additionally, using the clonogenic assay, we examined the effect of preincubation of Raji cells with pronase, collagenase, and DNase on the patterns of drug sensitivity.

The Raji cell culture line of Burkitt's lymphoma, in which the chemotherapy sensitivity has not been previously reported in the soft agar assay, was chosen for the following reasons: *a*) The Raji cell line retains most of the morphologic characteristics of the original tumor even after numerous passages in defined media (*13*). *b*) The analysis of cytogenetic, HLA, and viral antigenic expressions indicated no demonstrable difference between early and late passages of cell line (Hatanaka M, Hampar B: Unpublished data). *c*) The Raji cell line is derived from an untreated patient with Burkitt's lymphoma and thus is potentially useful for the in vitro screening of new anticancer drugs.

MATERIALS AND METHODS

Tumor cells.—The Raji cell line was obtained from Dr. Berge Hampar, NCI. The cells were cultured in McCoy's 5-A medium with 10% FCS (GIBCO, Grand Island, N.Y.) in a 5% carbon dioxide incubator at 37°C.

ABBREVIATIONS USED: Act-D = actinomycin D (dactinomycin); ADR = adriamycin; Ara-C = β-cytosine arabinoside; BLEO = bleomycin; CMRL-1066 = Connaught Medical Research Laboratory medium 1066; C×T = concentration times time product; FCS = fetal calf serum; FUra = 5-fluorouracil; L-PAM = L-phenylalanine mustard; Mit-C = mitomycin C; MTX = methotrexate; NCI = National Cancer Institute; PENTA = pentamethylmelamine; PLAT = *cis*-platinum II; VCR = vincristine.

Cells were diluted 1:30 (vol/vol) with fresh medium at 10- to 12-day intervals. The cells were used for drug sensitivity studies between the 7th and 10th days following passage at which time the concentration was 0.8-1.5×10^6 cells/ml.

Soft agar cultures.—The culture system for the cloning of Raji cells in a double-layer agar system was the same as that previously reported for the growth of human ovarian cancer cells (*4, 14*). This system is similar to that reported initially by Hamburger and Salmon (*1, 2*), with the exception that feeder cells were not used in the underlayers and 2-mercaptoethanol was not added to the upper layers. All cultures were performed in 35-mm petri dishes. The underlayer consisted of 1.0 ml of McCoy's 5-A medium, 10% FCS, other nutrients (*1, 2*), and 0.5% agar. The upper layer in which the tumor cells were added consisted of 1.0 ml of CMRL-1066 medium with 15% horse serum (both from GIBCO), other nutrients (*1, 2*), and 0.3% agar.

Drugs.—A total of 11 anticancer drugs were examined for their effect on colony formation by Raji cells. The drugs included examples from each of the major clinically useful drug categories: alkylating agents (L-PAM); antimetabolites (MTX, FUra, and Ara-C); antibiotics (ADR, BLEO, Mit-C, and Act-D): and vinca alkaloids (VCR) as well as drugs whose mechanism of action has not been fully elucidated (PLAT and PENTA). All drugs were obtained from the Investigational Drug Branch, NCI. Stock solutions of all drugs were prepared and aliquots frozen at −20°C and diluted prior to use.

Drug sensitivity studies.—The method for determination of drug sensitivities by means of the clonogenic assay has been previously described by investigators at the University of Arizona Cancer Center (*6, 7*). Each of the drugs was tested at a minimum of three different dose levels, including a concentration at the peak plasma level achievable in patients receiving conventional drug doses. In addition, the effect on colony formation following exposure to a drug at the C×T as calculated by Alberts and Chen (*15*) was determined because this may more accurately reflect the pharmacologic disposition of the drug than the peak plasma level. The effect on colony formation was determined by the use of both a 1-hour drug exposure and a continuous exposure to the drug during the entire growth period in agar. One-hour exposure: From 3 to 8×10^3 Raji cells in 1.5 ml of McCoy's 5-A medium with 10% FCS were incubated for 1 hour at 37°C in the presence of the drugs at varying concentrations. The cells were washed twice with drug-free media, and the cell concentration was adjusted to 6×10^3 cells/ml. To 0.5 ml of the cells were added 2.2 ml of enriched CMRL-1066 and 0.3 ml of molten 3% agar. After mixing, the cells were plated in triplicate and incubated as described above.

Continuous exposure: The cell concentration was adjusted to 6×10^3 cells/ml in McCoy's 5-A medium with 10% FCS. To 0.5 ml of the cell suspension were added 1.9 ml of enriched CMRL-1066, 0.3 ml of the drugs at various concentrations, and 0.3 ml of 3% agar. The cells were plated and cultured as described above.

Examination of cultures.—Cultures were examined with an inverted phase microscope. Aggregates of 30 cells or more were counted as colonies. Colony counting was performed after 7, 10, and 14 days of incubation. For drug-treated plates, the results are expressed as the mean percent survival (± SE) of colonies compared with that of untreated controls.

Incubation of Raji cells with enzymes.—A 1-ml suspension of cells containing 3-8×10^5 cells was centrifuged, and the supernatant was discarded. The pellet was resuspended in 1.0 ml of an enzyme mixture at a final concentration of 0.02% collagenase (215 U/ml; Sigma Chemical Co., St. Louis, Mo.), 0.02% DNase (1,775 Kunitz U/ml; Sigma Chemical Co.), and 0.05% pronase (4.4 U/mg; Sigma Chemical Co.) (*11*) in McCoy's 5-A medium without FCS. The cells were incubated for 1 hour at 37°C and washed twice with McCoy's 5-A medium with added FCS. The cells were resuspended in 1.5 ml of McCoy's 5-A medium and exposed to drugs for 1 hour as described above. Raji cells that were not incubated with the enzyme mixture were exposed to the same drugs in parallel with the enzyme-incubated cells.

RESULTS

Growth of Raji Cells in Soft Agar

Raji cell doublings were observed by the 2d or 3d day after plating. Between days 2 and 5, when cell counts in aggregates could be determined, the doubling time was approximately 24 hours. By day 15 of growth the diameters of the colonies remained essentially unchanged. The mean plating efficiency of 59 control samples was 29.8±1.39% (SE), and there was a linear relationship between the number of cells plated over a range of 10^2 to 3×10^4 cells and the number of colonies.

Drug Sensitivity Testing

One-Hour Exposure

The effects of a 1-hour exposure to anticancer agents on colony formation of Raji cells are summarized in table 1, and representative dose-response curves for the different classes of drugs are presented in text-figure 1. Colony suppression was observed with the antibiotics, the vinca alkaloid, PLAT, and the alkylating agent L-PAM. In contrast, no colony suppression was observed with either PENTA or any of the antimetabolites under the standard conditions for a 1-hour exposure.

All the antibiotics demonstrated a linear dose-response effect on colony formation. ADR was the most active antibiotic tested; a 1-hour exposure at 0.025 µg/ml (equivalent to 2% of the achievable C×T) produced a 90% suppression of colony formation. In contrast, BLEO produced only a 30% suppression at a dose corresponding to the C×T level. Act-D and Mit-C had intermediate suppressive effects with an 82 and a

[a] Drugs were incubated with Raji cells for 1 hr, and the effect on colony formation was compared to colony formation of untreated controls.

91% reduction, respectively, in colony formation at the C×T level. VCR, PLAT, and L-PAM had quantitatively similar dose-response curves as those for the antibiotics. VCR and PLAT both produced an 80% suppression of colony formation at the C×T level, whereas L-PAM produced a similar degree of suppression at only 20% of the C×T dose level.

The antimetabolites, conversely, had no effect on colony formation under these conditions even at dose levels 1.5–2.0 times greater than the achievable C×T level. PENTA also had no suppressive effects on colony formation following a 1-hour exposure even at a concentration of 50 µg/ml.

Continuous Exposure

The effect of continuous drug exposure during the 14-day incubation period on colony formation was compared to the suppression produced by a 1-hour drug exposure. The C×T for continuous drug exposure, even at the lower doses, was greater than the C×T for a 1-hour exposure at the highest doses used in the short-term incubations due to the markedly longer incubation period. Three patterns of drug sensitivity were observed (table 2): *a*) increased colony suppression with continuous exposure, *b*) colony suppression observed only with continuous drug exposure, and *c*) the same degree of suppression with either a 1-hour exposure or continuous exposure.

Six drugs that produced colony suppression with a 1-hour incubation produced a further suppression with continuous drug exposure. Included in this group were the four antibiotics, VCR, and PLAT. The increase in suppression with continuous drug exposure was most marked with Act-D, BLEO, and Mit-C. A 1-hour exposure to Act-D at 0.05 µg/ml produced a 20% reduction in colony formation, whereas continuous exposure at a concentration of only 0.001 µg/ml resulted in complete suppression of colony formation. With BLEO, a 1-hour exposure at 20 µg/ml produced the same degree of suppression (25% colony survival) as did continuous exposure at 0.1 µg/ml. With Mit-C a similar degree of suppression (31 and 21% colony survival) was observed with a 1-hour exposure at 0.5 µg/ml and with continuous exposure at 0.01 µg/ml.

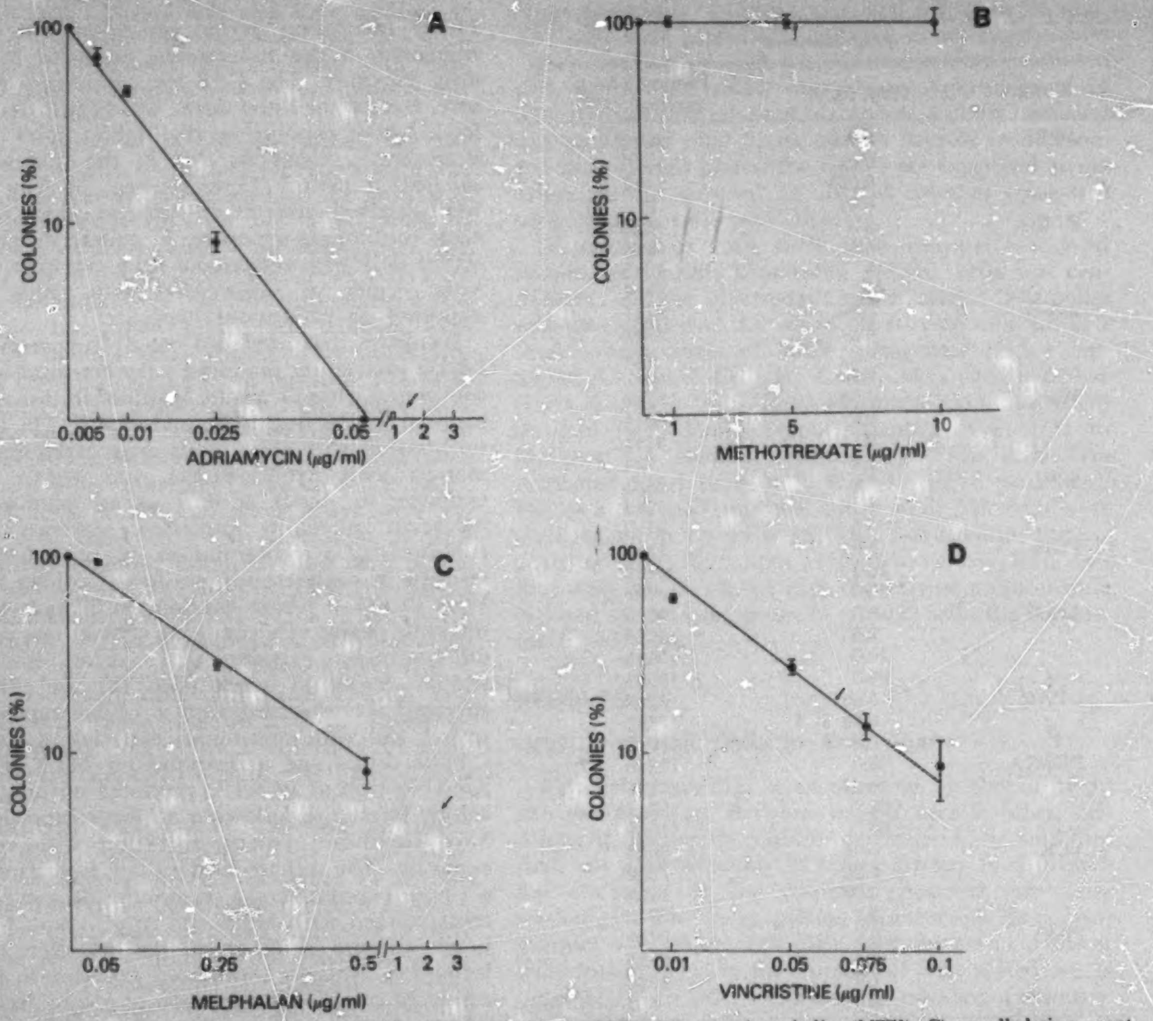
Four drugs, the antimetabolites MTX, FUra, and Ara-C as well as PENTA, produced no suppression of colony formation following a 1-hour exposure but did have significant colony reduction with continuous exposure. The difference in colony formation between a 1-hour exposure and a continuous drug exposure was most marked with MTX and Ara-C. With MTX, a 1-hour exposure at 10 µg/ml had no effect on colony formation, whereas continuous exposure to 0.1 µg/ml produced complete suppression of colony formation. A 1-hour exposure to Ara-C at 25 µg/ml produced no effect on colony formation, whereas continuous exposure at 0.5 µg/ml produced complete suppression.

PENTA produced a dose-dependent reduction in colony formation with continuous exposure, whereas no effect was observed with a 1-hour exposure. Continuous exposure at 50 µg/ml resulted in 5% colony survival; this same dose was ineffective with a 1-hour exposure.

The third type of effect comparing 1-hour and continuous drug exposure was observed with only one of the tested drugs. L-PAM had the same degree of suppression with both a 1-hour exposure and continuous exposure.

Effect of Preincubation With Enzymes on Colony Formation and Drug Sensitivity

Text-figure 2 demonstrates the relationship between the length of incubation of Raji cells with the enzyme mixture and the subsequent ability of the cells to form colonies in soft agar. A 30-minute incubation produced



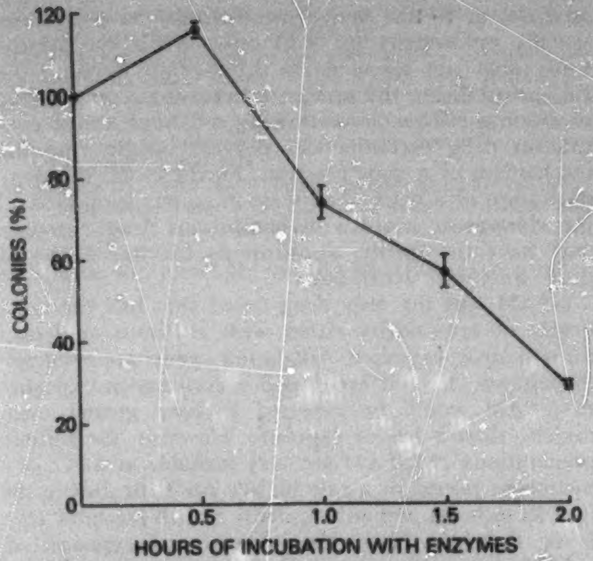
TEXT-FIGURE 1.—Effect of representative anticancer agents: A) an antibiotic (ADR); B) an antimetabolite (MTX); C) an alkylating agent [L-PAM (melphalan)]; and D) a vinca alkaloid (VCR) on survival of colony-forming cells following a 1-hr exposure at the concentrations given on the *abscissa*. Results are expressed as the mean (± SE) percent survivals of untreated controls. *Arrows* indicate clinically achievable C×T levels.

a 16% increase in colony formation compared to cells that were not exposed to digestive enzymes. However, after a 1-hour incubation, the colony formation had decreased to 74% of control, and by 2 hours there was only a 29% survival of colony-forming cells. Raji cells do not proliferate in serum-free medium, and the marked decrease in colony formation observed with a 2-hour incubation with enzymes in a serum-free medium may reflect the absence of required nutrients.

The effect of a 1-hour enzyme incubation on the subsequent pattern of anticancer drug sensitivity is summarized in table 3. Preincubation of the cells with enzymes did not appreciably alter the dose-response curves to six drugs that were tested with the use of 1-hour drug exposure.

DISCUSSION

The Raji lymphoma cell line is a suitable model system in which to study the effects of anticancer drugs on the ability of tumor cells to form colonies in soft agar. Observations made regarding drug sensitivities of Raji cells may have applicability in the optimization of the conditions currently used to determine drug sensitivities of fresh human tumors cloned in agar. The results of the present study demonstrate that the length of drug exposure can be an important determinant of a drug's cytotoxicity as measured by the effect on colony formation. Furthermore, the results also suggest that established human tumor cell lines may be useful for the screening of new anticancer drugs. If it can be



TEXT-FIGURE 2.—Effect on colony formation of Raji cells incubated with an enzyme mixture consisting of 0.02% collagenase, 0.02% DNase, and 0.05% pronase. Results are the mean (± SE) percent survivals of untreated controls.

determined that established cell lines retain the same drug sensitivity spectrum as that present in the original tumor when measured by the clonogenic assay, then for new drug screening, the higher efficiency of cell lines and the ability to culture large volumes of cells would make cell lines preferable to fresh tumor explants, which frequently may not produce sufficient colonies for a large drug-screening program.

The Raji cell line has a high cloning efficiency (30%) in soft agar under the same conditions currently in use for the human tumor clonogenic assay. In that regard, the Raji cell line is different from solid human tumors that have a cloning efficiency usually between 0.001 and 0.1% (*2, 4, 10*). The patterns of drug sensitivity observed with the Raji cell line therefore may be different than those observed in the human tumor stem cell assay. In addition, the Raji cells grow in suspension and are readily separated into single cells. In contrast, epithelial tumor cells are frequently tightly connected, and enzymatic incubation of Raji cells and epithelial tumor cells may produce different effects on cell membranes and subsequent drug sensitivities. In addition, tumor biopsy specimens contain a heterogeneous population of cells compared to homogeneous Raji cells in culture, and an enzyme incubation may produce differing effects on the various cells present in fresh tumor specimens. Accordingly, the observations made regarding the effect of enzymes on chemotherapy sensitivity and the effect of the length of incubation on the pattern of drug sensitivity in Raji cells need to be confirmed in the human tumor stem cell assay with fresh tumor specimens.

With a 1-hour drug exposure, dose-response relationships were observed with seven of the drugs tested including all the antibiotics, the alkylating agents, and VCR. Four drugs, all the antimetabolites plus PENTA, had no effect on colony formation following a 1-hour drug exposure. However, with continuous exposure to the drugs, the antimetabolites produced a marked suppression of colony formation. MTX produced a complete suppression of colony formation even at a concentration of 0.1 μg/ml compared to no suppression at a concentration of 10 μg/ml and a 1-hour drug exposure. The fact that no dose-response relationships were observed with continuous exposure to the antimetabolites indicates that all the doses used in the continuous-exposure studies produced a C×T that was cytotoxic. The marked differences in MTX cytotoxicity observed with a 1-hour and continuous drug exposures

[a] Raji cells were incubated with an enzyme mixture of collagenase (0.02%), DNase (0.02%), and pronase (0.05%) for 1 hr followed by a 1-hr drug exposure.

may be the result of the following factors: *a*) MTX is an S-phase-specific drug, and its cytotoxic effects, which are due to the inhibition of dihydrofolate reductase, will be observed only with prolonged exposure to cells as they go through the cell cycle. *b*) MTX enters cells by a rapid carrier-mediated, active transport system and is also extruded by an active efflux mechanism that is most effective in an MTX-free environment. *c*) Folates present in calf serum used in the media may have overcome the effects of a 1-hour exposure to MTX but were not present in sufficient quantity to overcome the cytotoxic effects of continuous exposure. *d*) The active form of intracellular MTX may be polyglutamate derivatives. In cultured human breast cancer cells after 24 hours of incubation, 70% of the intracellular MTX exists as polyglutamates (*16*). Removal of extracellular MTX will favor efflux of the drug instead of formation of polyglutamates.

In a similar manner, the lack of colony suppression observed with a 1-hour drug exposure, compared to continuous incubation of the antimetabolites FUra and Ara-C, is likely to be predominantly due to the S-phase-specific cytotoxic nature of these drugs, although other factors such as intracellular metabolism may also require prolonged exposure to enhance cytotoxicity (*17*).

Neither the mechanism of action nor the nature of the cytotoxic metabolites of the S-triazines hexamethylmelamine and PENTA has been fully determined (*18, 19*). The marked difference in cloning efficiency of Raji cells following a 1-hour or a continuous drug exposure with PENTA suggests that *a*) the Raji lymphoma cell line can slowly metabolize PENTA to an active intermediate, or *b*) the active metabolite(s) have S-phase-specific cytotoxicity for Raji cells. While the present study does not allow us to differentiate between the two possibilities, the results indicate that comparisons of cloning efficiencies following a 1-hour and a continuous drug exposure can provide insight into the mechanism of a drug's action. Furthermore, the demonstration of a marked decrease in colony formation in the clonogenic assay with continuous drug exposure may have therapeutic applications for the design of drug treatment schedules.

L-PAM was the only drug tested that had the same degree of cytotoxicity either with a 1-hour or a continuous drug exposure. Alkylating agents are cytotoxic throughout the cell cycle, and a continuous exposure to L-PAM would be expected to have greater cytotoxicity than a 1-hour exposure. However, the soluble preparations of L-PAM are very unstable at 37°C, and hydrolysis occurs at a rate of 50% per hour during the first 30 minutes and subsequently at 30% per hour (*20*). It is therefore likely that continuous exposure to L-PAM did not produce any further increase in the cytotoxicity of a 1-hour exposure due to a rapid degradation to an inactive form of the drug.

Antitumor Activity of Picolinic Acid in CBA/J Mice[1, 2, 3]

Susan W. C. Leuthauser,[4] **Larry W. Oberley,**[4, 5] *and* **Terry D. Oberley**[6, 7]

ABSTRACT—The growth of a solid tumor induced by im implantation of Ehrlich ascites tumor cells in inbred CBA/J mice was retarded by treatment with an iron chelator, picolinic acid (PLA). Survival of the mice was also significantly increased after PLA treatment. However, the iron chelator deferoxamine had no such effects; tumor growth was slightly enhanced, and survival was decreased.—JNCI 1982; 68:123-126.

A nicotinic acid analog, PLA (NSC-171), is a metabolite of tryptophan (*1*). The function of this naturally occurring bidentate metal chelator (*2*) is still unknown. PLA has been found to facilitate the absorption of zinc from the intestine (*3*) and the binding of Fe^{3+} and Zn^{2+} (*4*). In the presence of PLA, spore formation by *Bacillus subtilis* and growth of *Escherichia coli* were inhibited (*5, 6*). NRK cells were reversibly arrested at the G_1 stage of the cell cycle when PLA was added to the culture media (*4, 7-9*). Growth of transformed NRK cells was also arrested by PLA. However, this G_1 block was not reversible in transformed NRK cells (*10, 11*). Upon removal of this block the transformed cells progressed through S- and G_2 phases and then died. Fernandez-Pol (*4*) and Fernandez-Pol and Johnson (*10*) proposed that this differential response may involve NAD metabolism, cyclic AMP interference, or the differences in trace metal requirement between normal and transformed cells. Analogs of PLA have been shown to inhibit tumor growth in vivo (*12-14*). PLA has been tested in a variety of rodent experimental tumor systems (*15*). No antitumor effect was observed when PLA was administered ip. This study is designed to investigate the effect of PLA on the growth of a solid tumor.

MATERIALS AND METHODS

Ehrlich ascites tumor cells were maintained intraperitoneally in inbred adult female CBA/J mice (The Jackson Laboratory, Bar Harbor, Maine) by weekly transfers into new hosts. Solid tumors were induced by im inoculation of 5×10^6 cells into the right flanks of 8- to 12-week-old CBA/J female mice. Cell counts were done with a Coulter Model B cell counter. Mice implanted with Ehrlich cells subsequently developed solid tumors at the injection sites. Diameters of the tumor-bearing legs were determined with a vernier caliper by two-dimension measurements of the affected limbs.

The mean and standard error of the limb size in each treatment group were determined. There were 24 mice in each group. Significance of the difference between the 2 treatment groups was determined by Student's *t*-test. Survival times of these tumor-bearing mice were also used as an end point for the effectiveness of the treatment. Survival curves were analyzed by Mantel-Cox's Generalized Savage Test.

PLA (α-picolinic acid) was purchased from Sigma Chemical Co., St. Louis, Mo.; DFO (Desferal) was obtained from Ciba-Geigy Corp., Summit, N.J. In preliminary studies, 5 mice/group were given doses of 1, 2.5, or 5 mg PLA/0.1 ml saline daily for 5 consecutive days. For the PLA survival studies, a standard dose of 2.5 mg PLA/0.1 ml saline or saline alone was given to 24 mice in each treatment group. Tumor-bearing mice were PLA treated with 5 daily doses or a total of 10 doses (on days 0, 2, 4, 7, 9, 11, 14, 16, 18, and 21). The first dose was given at the same site and immediately after inoculation of cells. In addition to the PLA-treated groups, treatment groups included mice given saline or 2.5 or 5 mg DFO daily for 5 days. Each of these 3 groups also had 5 mice.

RESULTS

A dose-response study (text-fig. 1) showed that 1 mg PLA/day for 5 days produced a 29% reduction in the diameter of the tumor-bearing leg by day 10. However, when the daily dose was increased to 2.5 mg, the reduction in the diameter of the tumor-bearing leg was increased from 29% to 40% ($P<0.001$, compared to saline-treated controls). Additional increases in the daily dose of PLA caused little further reduction in the size of the tumor-bearing leg, but at these doses, kidney damage occurred (Oberley TD: Manuscript in preparation). Therefore, the dose chosen for this study was 2.5 mg.

ABBREVIATIONS USED: DFO = deferoxamine; NRK = normal rat kidney; PLA = picolinic acid.

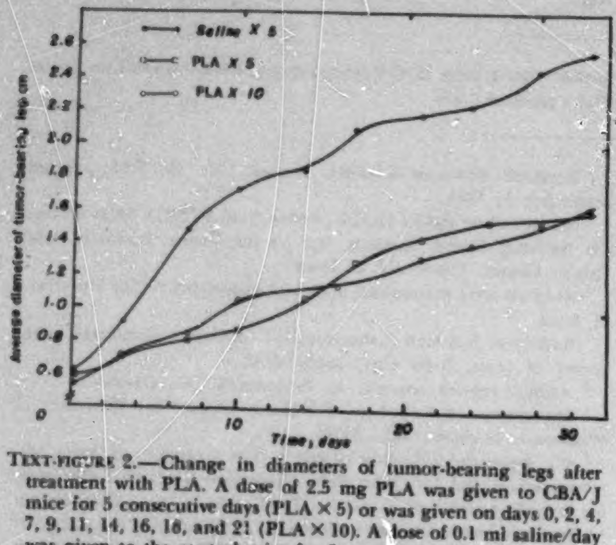
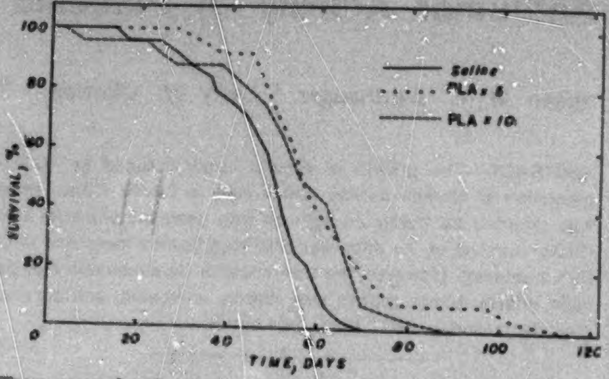
TEXT-FIGURE 1.—Response of Ehrlich ascites tumor in CBA/J mice to various doses of PLA. Diameters of tumor-bearing legs were measured as a function of time after 5 consecutive daily doses of saline or PLA. There are 5 mice in each treatment group.

Text-figure 2 shows the change in tumor-bearing leg diameters as a function of time after implantation. The various groups received different treatments. The control group received 5 daily doses of 0.1 ml of saline im. When 5 doses of 2.5 mg PLA were administered, a 25% reduction in the tumor-bearing leg diameter was observed by day 31 (27 days after the last treatment). When 10 doses of 2.5 mg PLA were given in a period of 22 days (on days 0, 2, 4, 7, 9, 11, 14, 16, 18, and 21), the reduction in the tumor-bearing limb diameter was unchanged by this additional treatment.

The antitumor activity of another iron chelator, DFO, was also tested in this tumor system. This compound is used clinically to treat iron poisoning; the maximum recommended im dose for adults is 6 g/day. When 2.5 or 5 mg of DFO (1.5 and 3 times the maximum recommended human dose) was given to these tumor-bearing mice daily for 5 days, no significant reduction in the tumor-bearing leg diameter was observed, as compared to the control; in contrast, growth of the tumor was slightly enhanced by DFO treatment, and the treated animals died faster than did the controls.



TEXT-FIGURE 2.—Change in diameters of tumor-bearing legs after treatment with PLA. A dose of 2.5 mg PLA was given to CBA/J mice for 5 consecutive days (PLA × 5) or was given on days 0, 2, 4, 7, 9, 11, 14, 16, 18, and 21 (PLA × 10). A dose of 0.1 ml saline/day was given to the control mice for 5 consecutive days (Saline × 5). There are 24 mice in each treatment group.



TEXT-FIGURE 3.—Survival of PLA- or saline-treated tumor-bearing CBA/J mice at the same dose schedules as in text-fig. 2. There are 24 mice in each treatment group.

Survival of the PLA-treated tumor-bearing mice was significantly increased. Text-figure 3 and table 1 show that the mean survival was increased from 49 to 62 days, or 127% that of the control ($P=0.001$), for the group receiving 5 doses and to 56 days, or 114% of the control ($P=0.01$), for the group receiving 10 doses. Median survival of both treatment groups was increased from 51 to 56 days, 110% that of control. Median survival data between the 2 PLA-treated groups remained the same, a further indication that additional PLA had no positive effect on the animals as was true for tumor size reduction.

No significant weight loss was observed in PLA-treated mice as compared to the saline-injected controls, suggesting that 1 group had not eaten less than had the other. The most significant change between the saline-treated and PLA-treated animals was the difference in maximum survival which, as shown in table 1, was increased from 70 to at least 112 days in the group receiving 5 doses (160% of the control) and from 70 to 89 days in the group receiving 10 daily

TABLE 1.—*Summary of survival data for CBA/J mice*

Treatment group, No. of doses[a]	Survival, days		
	Mean ± SE	Median	Maximum
Saline	49±3	51	70
PLA, 5	62±6	56	112[b]
PLA, 10	56±5	56	89

[a] *See* "Materials and Methods" for dose schedules.
[b] Experiment was terminated.

doses (127% of control). Thus, although the change in mean or median survival was not impressive, the change in maximum survival was quite substantial, which indicates an increase in longer term survivors. One mouse in the PLA-treated group appeared tumor-free at 112 days, at which time the experiment was terminated.

Autopsies on all tumor-bearing mice revealed that massive lung metastasis was invariably the cause of death. Kidney necrosis was observed in some of the PLA-treated mice. The effect of PLA on the kidneys of normal nontumorous mice will be reported elsewhere (Oberley TD: Manuscript in preparation).

DISCUSSION

Our results indicated that PLA has a positive antitumor activity in this experimental tumor model. PLA-treated mice had significantly slower increases in tumor size. The increases in mean and median survivals were not impressive, but the increase in maximum survival was substantial. Since the PLA-treated mice showed no weight difference when compared with the control group, it is unlikely (although not definitely proved) that the effects are due to reduced food intake and subsequent weight loss. These results contrast with those of previous studies in which PLA was ineffective in several rodent tumor systems when either tumor size or animal survival was used as a therapeutic indicator (*15*). One possible difference between our study and the previous ones is that we used im rather than ip injections. When given ip, PLA is rapidly excreted into the urine, with a half-life of 6 hours (*1*). PLA is probably excreted more slowly with the im injection used in this study.

The mechanism of action for the arrest of NRK cells by PLA in G_1 remains unknown. Fernandez-Pol and co-workers (*4, 10, 11*) proposed alteration of cyclic AMP metabolism, NAD metabolism, or chelation of Fe^{3+}-Zn^{2+} as possible modes of action. Reduced tumor growth could be due to the inhibition or retardation of the cell proliferation process or to the reduction in the number of cycling cells. Text-figure 2 shows that the growth rates of the tumors from the saline-treated and the PLA-treated mice were very similar after the initial period during treatment. Since the slopes of the growth curves remained unchanged, the number of viable cycling cells was most likely reduced after PLA treatment.

Fernandez-Pol and co-workers have proposed that deprivation of iron might be responsible for tumor cell toxicity. If this were true, why does PLA have such a marked effect on tumor cell growth whereas twice as much DFO has none? There are several possibilities why DFO was not effective. DFO may have been excreted much more rapidly than was PLA, or it could have other toxic side effects. We tested DFO at three times the maximum recommended human dose, but it is possible that this dose is still not high enough in mice. Although this possibility seems unlikely, DFO might have the same effect as PLA has at a much higher dose.

Lastly, the cytotoxicity of PLA may involve generation of hydroxyl radicals via the Fenton reaction (*16*). Generation of ·OH in an aqueous solution in the presence of PLA, Fe^{2+}, H_2O_2, and superoxide was detected by the electron spin resonance technique (Buettner GR, Oberley LW: Unpublished observation). DFO has been shown to be a powerful inhibitor of ·OH generation (*17*). Possibly, the difference in the response of the tumor to PLA and DFO is due to the ability of these agents to generate ·OH. In this tumor model, the activity of a superoxide scavenger, superoxide dismutase, is depressed (*18*). Since catalase and glutathione peroxidase activities are also reduced in tumors, such depletion in protective enzymes may lead lead to a surplus of O_2^- and H_2O_2; with the availability of PLA-Fe complexes, the toxic ·OH could be produced readily. Obviously, further studies are needed to confirm this hypothesis.

Equivalency of Endothelial Cell Growth Supplement to Irradiated Feeder Cells in Carcinogen-Induced Morphologic Transformation of Syrian Hamster Embryo Cells[1]

Charles H. Evans[2] *and* **Joseph A. DiPaolo**[2,3]

ABSTRACT—Endothelial cell growth supplement (ECGS), an extract of bovine neural tissue with growth-promoting properties for human endothelial and epithelial cells and for mouse BALB/c fibroblast-like cells, can be substituted for feeder cells in a quantitative 7-day Syrian hamster embryo cell colony in vitro model of carcinogenesis. Inclusion of 50 or 100 μg ECGS/ml medium throughout the 7-day growth period produced results equal to those obtained with feeder cells. The frequency and morphology of normal fibroblast colonies and carcinogen-induced morphologically transformed cell colony growth in the presence of ECGS were similar to those in the presence of feeder cells. A positive dose-response relationship in transformation by benzo[a]pyrene occurred. The frequency of transformed colonies following UV irradiation and treatment of the cells with the cocarcinogenic tumor promoter 12-*O*-tetradecanoylphorbol 13-acetate was greatly augmented, and lymphotoxin, a lymphokine with anticarcinogenic activity, reduced transformation. Thus ECGS can substitute for feeder cells in supporting in vitro transformation and eliminates a potential complex source of variability for studies where interaction(s) with feeder cells are a consideration. The mechanics of this model system was simplified, and its versatility for the study of physiologic, carcinogenic, and other pathophysiologic processes was broadened.—JNCI 1982; 68: 127–131.

Carcinogen-induced morphologic transformation of early passage Syrian HEF strains in the conventional 7-day quantitative cell colony assay of carcinogenesis has been dependent upon the inclusion of X-irradiated feeder cells or conditioned medium to facilitate the growth of a relatively small number of cells seeded for colony formation in the study of carcinogenesis, cocarcinogenesis, and anticarcinogenesis (*1–3*). In addition to the logistic complexity and/or inconvenience of access to an irradiation source or of preparation of conditioned medium, both feeder cells and conditioned medium introduce potential additional variables and sources of positive or negative interaction(s) in each experiment. For example, feeder cells or conditioned medium have the potential to provide crossfeeding and other metabolic and/or inactivating or interfering effect(s) in the study of multiple interactions (*4–6*). For investigations where such interactions are undesirable or not permissible, it would be advantageous to have a nonliving and more constant substitute for feeder cells or conditioned medium.

A variety of growth factors, including FGF, epidermal growth factor, neural growth factor, platelet-derived growth factor, fibronectin, and ECGS, have been shown to enhance the growth of various cells (*7, 8*). Some of these growth factors or supplements hold promise as substitutes for the complex and frequently unknown variables resident in serum, feeder cells, and the plethora of ingredients in the manifold cell culture models developed for the study of normal and pathophysiologic conditions. For example, human endothelial cells produce a factor(s) that can replace the feeder cells in the growth of hybridoma cells for monoclonal antibody production (*9*). These human endothelial cell factors, however, are not commercially available, and their activities for other cells are unknown. Crude bovine brain extracts prepared at pH 8.5 contain potent mitogenic factor(s) for myoblasts, and the extracts may be useful for cloning cells or for accelerating the growth of slowly dividing cells (*10*). ECGS, a commercially available extract of bovine neural tissue, promotes the growth of human endothelial and epithelial cells and stimulates the growth of mouse Balb/3T3 cells (*11, 12*). This investigation demonstrates that ECGS can substitute for the feeder cells in the Syrian HEF colony in vitro model of carcinogenesis.

MATERIALS AND METHODS

Substitution of ECGS for feeder cells was studied in the HEF in vitro model of carcinogenesis in which the frequency of carcinogen-induced morphologic transformation is quantifiable and indicative of the cells' neoplastic potential (*1*). In each transformation experiment, secondary cultures of HEF, originally obtained from 12-day gestation fetuses of a single hamster and stored in liquid nitrogen as trypsinates of cell pools prior to any growth, were cultured and treated with carcinogens (*13*). Cell pools from three dams were utilized.

Tissue culture dishes (100 mm in diameter) were seeded with 10^7 freshly thawed cells in 10 ml DMEM

ABBREVIATIONS USED: BP = benzo[a]pyrene; DMEM = Dulbecco's modified Eagle's minimum essential medium; ECGS = endothelial cell growth supplement; FBS = fetal bovine serum; FGF = fibroblast growth factor; HEF = hamster embryo fibroblast(s); TPA = 12-*O*-tetradecanoylphorbol 13-acetate.

containing 3×10^{-6} *M* thymidine, 3×10^{-5} *M* hypoxanthine, and 10% FBS (medium) but no antibiotics, and the cells were grown at 37°C in a 10% CO_2 water-saturated atmosphere of PHARM-AIR (Pall Trinity Micro Corp., Cortland, N.Y.) purified compressed air (*14*). Three lots of serum (#R6, R8, and 33K) were included in the study. Three days after removal from nitrogen and culture, the cells were trypsinized and 100-mm dishes were seeded with 2×10^6 cells in 10 ml medium. After 48 hours the cells were trypsinized, and 300 cells with 6×10^4 X-irradiated sister culture cells for a feeder layer were seeded per 60-mm dish in 4 ml medium. Feeder cells were prepared by removal of 5 ml of medium from a 2-day secondary culture of cells and delivery of 2,000 R of 100-kV peak X-rays from a Torex model 120 X-irradiator (Torr X-Ray Corp., Van Nuys, Calif.) immediately prior to plating. Nonirradiated cells were suspended in medium alone or with ECGS-containing medium for comparison of growth and transformation to cells cocultivated with feeder cells. Three lots (#797-8, 1084-9, and 1076-591) of ECGS were purchased (Collaborative Research, Inc., Waltham, Mass.) and stored at −20°C until dissolved in sterile Milli-Q deionized water, Dulbecco's phosphate-buffered saline, or medium without serum immediately prior to addition to the cells. ECGS lots #797-8, 1084-9, and 1076-591 had been stored for 2 years, 1 month, and 4 months, respectively, before use.

Twenty-four hours after cells were seeded, another 4 ml of medium containing BP and an appropriate additional ECGS to maintain the initial ECGS concentration were added or the medium was removed, the cells irradiated with 254 nm UV light, and the dishes refed with 8 ml of medium with or without ECGS. TPA (Vega Biochemicals, Tucson, Ariz.) was added 48 hours after UV irradiation as described for TPA enhancement of *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine transformation (*15*). Lymphotoxin, a lymphokine with antitransforming activity for HEF, was prepared, concentrated, and equilibrated with phosphate-buffered saline (pH 7.4) by diafiltration on Amicon YM10 membranes (Amicon Corp., Danvers, Mass.), and added to the cells 48 hours after BP treatment (*3*). Six dishes were treated with each concentration of carcinogen, ECGS, or other chemical in each experiment. Six days after carcinogen treatment, the dishes were stained and the cell colonies examined for morphologic transformation, a random piled up layering of spindle-shaped fibroblasts not observed in noncarcinogen-treated cultures that correlates with the ability of the cells to grow as tumors in vivo (*1*).

RESULTS

The inclusion of ECGS in the culture medium in place of X-irradiated feeder cells resulted in equivalent growth and carcinogen-induced morphologic transformation of Syrian HEF (fig. 1). At a concentration of 50 or 100 μg ECGS/ml medium, colony formation and transformation frequencies were similar to those observed in the presence of feeder cells (table 1). The growth of control (solvent treated) cells in the presence of 50 μg ECGS/ml culture medium was also equivalent to growth with feeder cells (table 2). Similar results were obtained with each of three lots of serum, with three lots of ECGS, and with three pools of HEF.

TABLE 1.—*Substitution of ECGS for feeder cells in the BP induction of morphologic transformation of Syrian HEF*[a]

Culture medium supplement	Colony formation, %	Transformed colonies/dish
ECGS, μg/ml medium		
0	10.8±0.4	0.2±0.1
5	11.2±0.8	0.8±0.1
10	15.4±0.4	0.7±0.1
25	14.3±0.7	0.8±0.2
50	16.3±0.6	1.8±0.1
100	15.7±1.0	2.0±0.2
Feeder cell layer	13.2±0.7	1.2±0.1

[a] Three hundred HEF (pool F80-5) in 4 ml DMEM–10% FBS (lot #R8) medium containing ECGS (lot #1084-9) at the indicated concentrations or 6×10^4 X-irradiated HEF for feeder were seeded per 60-mm tissue culture dish. One day later, 4 ml of additional medium containing 5.0 μg BP/ml was added. Colonies (>2 mm) were enumerated and examined for morphologic transformation 7 days after seeding. Results are means±1 SE.

In the presence of ECGS the frequency of morphologic transformation increased with increased carcinogen concentration as previously established by use of feeder cells (table 3). ECGS also supported TPA enhancement of the transformation induced by UV irradiation and the inhibition of transformation by lymphotoxin to an extent similar to that observed in the presence of feeder cells (table 3).

TABLE 2.—*Comparison of medium alone, X-irradiated feeder cells, or ECGS in BP induction of morphologic transformation of Syrian HEF*[a]

Chemical treatment	Medium alone		Feeder cells		ECGS	
	CF	T/D	CF	T/D	CF	T/D
Expt 1						
BP	10.3±0.7	0.7±0.1	13.1±0.5	2.5±0.1	17.9±0.4	1.8±0.1
Solvent (alone)	14.0±0.5	0±0	21.4±0.7	0±0	20.8±0.8	0±0

[a] Three hundred HEF (pool F80-5) in 4 ml DMEM–10% FBS (lot #R6) medium containing 50 μg ECGS (lot #797-8)/ml, 6×10^4 X-irradiated HEF for feeder, or neither one were seeded per 60-mm tissue culture dish. One day later, 4 ml of additional medium containing 5.0 μg BP/ml or solvent only were added. BP was initially dissolved in acetone, and the final solvent concentration in the dish was 0.04%. Colonies were enumerated and examined for morphologic transformation 7 days after seeding. Mean values±1 SE are presented of the percent colony formation (CF) and the number of transformed colonies/dish (T/D).

TABLE 3.—*Equivalency of ECGS with feeder cells in carcinogen and cocarcinogen-induced morphologic transformation of Syrian HEF*

Treatment[a]	Transformed colonies/dish	
	Usual response in the presence of feeder cells[b]	With ECGS substituted for feeder cells
BP, 0 μg/ml	0	0
BP, 1 μg/ml	1.3–2.0	0.9±0.3
BP, 2.5 μg/ml	2.2–3.1	1.7±0.3
BP, 5.0 μg/ml	2.2–4.2	2.7±0.5
UV irradiation, 3.0 J/m^2	0.1–1.6	0.1±0.1
UV irradiation, 3.0 J/m^2, plus TPA, 50 ng/ml	15- to 20-fold increase	1.3±0.4
TPA (alone), 50 ng/ml	0	0
BP, 2.5 μg/ml	2.2–3.1	1.7±0.4
BP, 2.5 μg/ml, plus lymphotoxin, 12.5 U/ml	50–100% inhibition	0.8±0.2
Lymphotoxin (alone), 12.5 U/ml	0	0

[a] HEF were seeded and treated 1 day later with carcinogen as described in table 2. TPA when added was done so 2 days after UV irradiation. Lymphotoxin when added was done so 2 days after BP. The FBS used in these expts was lot #32K, and the ECGS was lot #1076-591. Two pools of cells were used: F80-35 for the BP and F79-32 for the UV treatments.

[b] For BP, *see* (*3*), (*13*), (*14*), and (*16*); for UV irradiation, *see* (*3*), (*13*), (*16*), and (*17*); for TPA enhancement, *see* (*18*); and for lymphotoxin inhibition, *see* (*3*). UV irradiation transformation is particularly dependent upon the lot of FBS, frequently requiring 15 or 20% FBS to obtain the higher transformation frequencies within the indicated range. All expts in the present investigation were performed with the use of 10% FBS.

DISCUSSION

The current results demonstrate that ECGS can replace feeder cells in quantitative in vitro studies of carcinogenesis with the use of HEF. This will facilitate investigations where questions of potential feeder cell cooperation, inhibition, or other effects are entertained. Substitution of ECGS for the feeder cells also allows investigators without access to an X-ray source to consider the use of this model system in their laboratories.

The observation that 50–100 μg ECGS/ml medium produces results equivalent to those in the presence of feeder cells is similar to the report that 100 μg ECGS/ml is optimal for the proliferation and differentiation of normal human bronchial epithelial cells in culture (*11*). Additional optimal concentrations may be found for other cells inasmuch as up to 300 μg ECGS/ml has been reported to be stimulatory for human endothelial and Balb/3T3 cell growth (*12*). For HEF transformation, however, it appears that 50 or 100 μg ECGS/ml yields results equivalent to the results by use of the standard number of feeder cells in the colony assay for carcinogen-induced morphologic transformation of HEF. The results suggest that the supportive role of feeder cells and conditioned medium may be due to the production of growth factors similar to, if not identical to, those in ECGS. The growth factors in ECGS have been partially defined and include FGF and other mitogenic and growth-promoting activities (*12, 19*). Because the components in ECGS are isolated, it will be of interest to determine which support cell colony formation (cell proliferation) and morphologic transformation as well as to establish the relationship of ECGS to the growth factors isolated from other tissues.

Effect of Thymectomy on Development of Lucké Renal Adenocarcinomas in Virus-Infected Leopard Frog Tadpoles[1, 2, 3]

Louise A. Rollins-Smith[4] *and* **Nicholas Cohen**[4, 5]

ABSTRACT—Thymectomy of very young leopard frog (*Rana pipiens*) larvae dramatically reduced in vitro lymphocyte responses to the mitogen phytohemagglutinin-P and prolonged survival of Lucké tumor alloimplants. However, tumor incidence in premetamorphic or metamorphosing frogs that had received injections as embryos of Lucké tumor herpesvirus (LTHV) was the same in thymectomized and normal immunocompetent animals. This result suggests that T-cell-mediated cytotoxicity does not prevent development of Lucké tumors in immunocompetent larvae and that if tumor-specific transplantation antigens appear, they may induce tolerance rather than destructive immunity in normal LTHV-infected larvae.—JNCI 1982; 68:133-138.

The Lucké renal adenocarcinoma of northern leopard frogs, *Rana pipiens,* provides an interesting model for the study of the development of cancer. The causative agent of the tumor is LTHV (*1, 2*). Among herpesvirus-related cancers, the Lucké tumor is unique because the tumorigenic phase of virus infection is distinctly separable from the virus-replicating phase; i.e., tumorigenesis occurs in the summer or under warm laboratory conditions, whereas virus replication occurs only in the winter or under cold (<9°C) laboratory conditions (*3-6*).

It has long been known that embryos and larvae of leopard frogs support growth of Lucké tumors better than do adults. Lucké (*7*) and Lucké and Schlumberger (*8*) showed that tumor allografts do not grow in the coelom, intramuscular space, or dorsal lymph sac of adults. These allografts survive only in the relatively "privileged" space of the anterior eye chamber (*9*). However, implanting tumor allografts in the dorsal tail fin of young larvae, Briggs (*10*) reported that nearly half showed "significant growth" at this site. Similarly, LTHV injected into adults does not seem to induce an incidence of primary tumors higher than that developing in uninoculated animals (*11*). However, LTHV injected into embryos does result in the development of a high proportion of tumors in late-stage larvae and metamorphosing juveniles (*12*). It has been generally assumed that the relative ease of transplantation or induction of tumors in embryonic and larval frogs may be due to a lack of "maturity" of the immune system. Surprisingly, few studies have been designed to examine this assumption. Since thymus-derived cells (T-cells) are generally thought to play some role in the maintenance or rejection of virus-induced tumors, an evaluation of tumor induction in virus-inoculated frogs that were tx during early larval life seemed a logical initial step in the determination of whether the immune response does play a role in the development of tumors in young frogs.

MATERIALS AND METHODS

Frogs.—Eggs were obtained from gravid female *R. pipiens* by the induction of ovulation according to standard methods (*13, 14*). We obtained sperm by mincing the testes from a mature male in several milliliters of 10% Ringer's solution (*13*). Embryos resulting from in vitro fertilization were reared at room temperatures (18-22°C) until they reached the appropriate stage for virus injection [stages 19-20 of Shumway (*15*)] or thymectomy [stages I-III of Taylor and Kollros (*16*)]. All larvae were reared in 4-liter containers (10 larvae/container). Their water was changed and they were fed boiled lettuce three times weekly.

Virus injections.—Two tumor-bearing frogs were held at 8°C for 4 to 5 months. Eosinophilic nuclear inclusions in a sectioned and stained tumor fragment confirmed the presence of viruses (*17*). A virus-containing mitochondrial fraction was prepared from each cold tumor according to the method of Tweedell (*12*). The mitochondrial precipitates from a 2.7-g tumor and a 1.8-g tumor were diluted in 13.5 ml and 9.0 ml, respectively, of 0.02 *M* phosphate buffer (pH 7.3) containing 0.24 *M* sucrose (PBS) (*12*) and stored at −70°C until used. Approximately 0.5-1 μl of the virus preparation, at full strength or at 1/10 and 1/100 dilutions in PBS, was injected into the left pronephric region of Shumway stages 17-20 embryos. A fine glass needle attached to a 100-μl Hamilton syringe was used. Each aliquot of virus preparation was kept on ice during the injection procedure and was used for no more than 3 hours.

Thymectomy.—The bilateral thymuses, which lie slightly caudal and ventral to the eye capsule, were

exposed, loosened with fine glass needles, and removed in fragments by suction with a fine glass micropipette at stage I, II, or III of Taylor and Kollros.

Assessment of tumor development.—In one experiment involving a weakly oncogenic virus preparation, virus-injected embryos were reared through metamorphosis until 6 months of age post fertilization. At that time, the surviving frogs were killed and examined with a dissecting microscope for tumors in the region of the mesonephros or pronephros. (When the pronephros becomes tumorous in larval life, it persists through metamorphosis.) All larvae that died before metamorphosis were also examined for tumor development. Tumor incidence was recorded only for those frogs that survived more than 2 months post fertilization. In a second experiment involving a strongly oncogenic virus preparation, all virus-injected embryos were killed at 2 months post fertilization and examined for tumors.

Assessment of effectiveness of thymectomy.—Nearly all larvae and metamorphosing juveniles were checked for a regenerated thymus at the time of death. Blood lymphocytes from some tx larvae that had not been given injections of virus were cultured with the T-cell mitogen PHA and their responses compared with those of cells from normal intact larvae of the same age and relative stages. For in vitro lymphocyte studies, blood was drawn by cardiac puncture from anesthetized larvae at 1 month post thymectomy. The blood was mixed with about 100 μl of Leibovitz (L-15) culture medium (GIBCO, Grand Island, N.Y.) diluted to amphibian tonicity (*18*). The diluted blood was then layered on Ficoll-Hypaque (approximate density, 1.090) (*19*) in UV irradiation-sterilized 400-μl-capacity plastic microfuge tubes and centrifuged at low speed ($\approx 500 \times g$) for 5 minutes in a Beckman microfuge. The mononuclear cells were drawn off, washed once, and cultured at a density of 5×10^4 small lymphocytes/ml in Linbro 96-well U-bottom microtiter plates (Flow Laboratories, Inc., McLean, Va). Each well contained 200 μl of L-15 culture medium supplemented with 100 U penicillin/ml, 100 μg streptomycin/ml, 1.25×10^{-2} *M* HEPES[6] buffer, 1×10^{-2} *M* sodium bicarbonate, 5×10^{-5} *M* 2-mercaptoethanol, and 1% heat-inactivated fetal calf serum (GIBCO) (*18*). The cultures were assayed for mitogen-induced DNA synthesis according to published procedures (*18, 20*). The final concentration of PHA (Difco Laboratories, Detroit, Mich.) was 8 or 10 μg/ml. Cultures were incubated in Mishell-Dutton boxes (Norbo Machine, Huron, S.Dak.) at 26°C for 3 days and gassed with 5% CO_2-95% air every 24 hours. Before being harvested with a precipitator (Otto Hiller Co., Madison, Wis.), the cells were exposed to tritiated thymidine (10 μCi/ml; sp act = 2 Ci/mmol; obtained from New England Nuclear Corp., Boston, Mass.) for 8 hours. For each larva tested, an average of background cpm for cells cultured in medium alone, an average of stimulated cpm for cells cultured with mitogen, and a stimulation index (stimulated counts/background counts) were computed. Usually, two or three replicate wells with lymphocytes alone and lymphocytes plus mitogen were plated. However, paucity of cells (especially in tx animals) sometimes limited us to one well that contained control cells and one that contained mitogen-treated cells per tadpole. The mean cpm for all the individual tadpoles were then averaged to determine the mean background counts and mean stimulated counts for the population of larvae.

Tumor allograft implantation.—Larvae, tx at stage I or II of Taylor and Kollros, and unoperated controls were allowed to develop to stage III or IV (20-35 mm in length). They were than implanted with approximately 1 mg of freshly excised Lucké tumor that had been previously cultured in the anterior eye chamber of an adult frog (*9*). Tumors were implanted into a pocket in the dorsal tail fin according to the method of Briggs (*10*). Tumor implants were examined at frequent intervals with a dissecting microscope.

RESULTS

The incidence of tumors and premalignant lesions developing in normal and tx frogs that had been inoculated as embryos with LTHV was not significantly different regardless of the relative oncogenicity of the virus preparation or the dilution injected (table 1). There were no striking size differences in the tumors observed in tx frogs compared to intact controls. In both groups, premalignant cystic lesions were usually detected at 2 months. They were small, usually vesicular, growths within an otherwise normal kidney. At later times, either solid tumors or premalignant vesicles converting to solid tumors were observed. No metastases were ever observed in either the tx or intact group.

To determine whether thymectomy results in an earlier onset of tumor development, we regrouped the data from experiment 1 such that the incidence of tumors developing in an approximately 2-month period

[6] 4-(2-Hydroxyethyl)-1-piperazine ethanesulfonic acid.

in normal and tx larvae that died before metamorphosis was compared with that developing in frogs that died during and after metamorphosis (a period of ≈2 mo) (table 2). The data in table 2 clearly show that most tumors were observed in both normal and tx frogs during and after metamorphosis. Further, tumor incidence did not differ significantly between normal and tx frogs in either the premetamorphic or postmetamorphic period for any virus dilution tested. In experiment 2 (table 1), all virus-injected larvae were killed 2 months after injection. Both intact and tx frogs were at early larval stages (IV–IX of Taylor and Kollros) (*16*). If thymectomy results in an earlier onset of tumor development, one would expect a higher incidence of tumors in these young tx frogs. Instead, we observed that the incidence of tumors was the same in intact and tx frogs. Thus the time of onset of tumor development seems to be related to the relative oncogenicity of the virus preparation used and does not seem to be affected by thymectomy.

Because there seems to be no difference in tumor incidence between normal and tx frogs, it is important to know the effectiveness of the thymectomy procedure. In experiment 1, most of the virus-inoculated tx frogs were examined under the dissecting microscope at the time of death for the presence of a regenerated thymus. Of 85 frogs autopsied, 75 (88.2%) had no trace of regenerated tissue. The others had less than one-fourth of the normal amount of thymus tissue. Thus the data from experiment 1 include data gathered from a few frogs that had a small amount of regenerated thymus tissue. These data are included because the frogs in question had severely impaired T-cell functions throughout most of the period of study, as evidenced by their diminished in vitro responses to the T-cell mitogen PHA (*see* below). In experiment 2, all virus-inoculated tx frogs were examined for regenerated thymus tissue at the time of death. About 66% were free of regenerated tissue. Those with evidence of thymus regeneration were excluded.

To determine to what extent early thymectomy impairs classical T-cell responses in this species, we studied PHA-induced lymphocyte proliferation in vitro and allograft rejection in vivo in normal and tx frogs. When tested at 1 month post thymectomy, lymphocytes from intact larvae responded significantly to PHA (average stimulated cpm about eight times background). Lymphocytes from tx larvae did not respond (text-fig. 1). Stimulation indices for cells from intact larvae ranged from 0.1 to 23.3 (median, 6.8). Stimulation indices for cells from tx larvae ranged from 0.6 to 3.9 (median, 0.9). At autopsy, all tx larvae included in these determinations were completely devoid of regenerated thymus tissue. Cells from animals with less than one-fourth of normal thymus tissue also responded poorly to PHA.

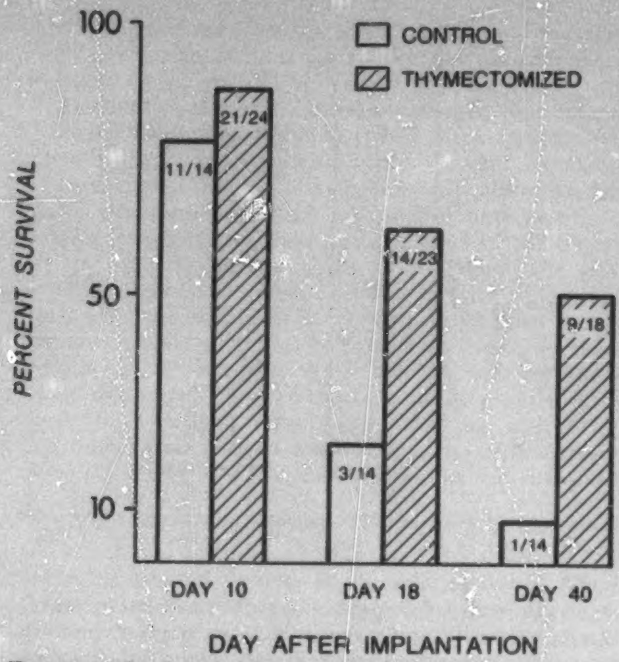
TEXT-FIGURE 1.—Average PHA responses of lymphocytes from intact control and tx larvae 1 mo post thymectomy (mean ± SE).

The ability of tx larvae to reject Lucké tumor allografts in the dorsal tail fin was also diminished relative to that of age-matched intact controls (text-fig. 2). Greater than 90% of intact larvae had rejected a tumor allograft before 40 days, whereas only about 50% of tx larvae had rejected their grafts by that time. Among those larvae that rejected their grafts, all had some degree of thymic regeneration at autopsy. This was an early experiment when we were still developing the technique of thymectomy. The effectiveness of the thymectomy procedure was greatly improved in subsequent experiments.

DISCUSSION

Complete thymectomy early in larval life effectively impairs both in vivo and in vitro responses that are attributed to T-cells in another anuran species (*21*) as well as in mammals. Thymectomy, however, had no effect on the incidence of tumors developing in virus-inoculated tadpoles. Thus normal intact larvae appear to be no better able to prevent tumor development than immunologically impaired larvae. Since the LTHV does not replicate at the temperatures at which frog larvae are reared (18–22°C), any destructive immune response would have to be directed against tumor-specific antigens and not against virus particles themselves. Nothing is known about the activity of the viral



TEXT-FIGURE 2.—Percent survival of tumor allografts in normal and tx larvae. *Numbers inside bars* indicate No. of tumor implants surviving/tadpoles implanted.

genome in LTHV-infected cells until tumors develop. Presumably, there is no expression of viral products. However, the viral genome in tumor cells clearly is not silent. Virus-specific messenger RNA is synthesized in both warm-temperature-phase and cold-temperature-phase tumors (*22*). Similarly, virus-associated membrane antigens have been detected on both cold-temperature-phase and warm-temperature-phase tumors (*23*). Whether these virus-associated antigens behave as TSTA is not yet known. By analogy with other virus-induced tumors (*24-26*), the Lucké tumor would be expected to be immunogenic and to elicit, in an immunocompetent host, cytotoxic effector T-cells directed against the virus-associated antigens. Thus we would expect a higher incidence of tumors in tx individuals if the cytotoxic T-cell system were important in controlling tumorigenesis.

The Lucké tumor developing in immunocompetent tadpoles, then, is paradoxical. Although it probably expresses TSTA, immunocompetent tadpoles and metamorphosing frogs are no better able to prevent tumor development than are their immunologically impaired siblings. Perhaps, at a high virus dose, the immune system of competent hosts is overwhelmed. If so, one would expect that at lower virus doses, there would be significantly fewer tumors in normal hosts compared to tx hosts. The most oncogenic virus preparation that we used induced tumors in about 95-100% of virus-inoculated frogs. Neither at full strength nor at a 10^{-1} dilution was there a significant difference in the incidence of tumors developing in intact frogs compared to tx frogs (table 1, expt 2). Comparable results were seen with a second virus preparation of weaker oncogenicity. At full strength, this preparation induced tumors in about 20% of hosts regardless of whether they were intact or tx. Even at a 10^{-1} or 10^{-2} dilution, the incidence of tumors was not significantly different in normal frogs compared to tx frogs (table 1, expt 1).

Survival of immunogenic tumors such as those that are virus induced probably depends on a balance between antitumor responsiveness and protumor immunosuppression (*27*). In the frog tadpole the net effect of such opposing immune responses may favor suppression. There is considerable evidence from research with another anuran amphibian, the South African clawed frog (*Xenopus laevis*), that the entire larval period, like the neonatal period in mice (*28*), is a time in which specific tolerance to alloantigens is much more easily induced than in the adult postmetamorphic period (*29*). Prolonged or indefinite acceptance of skin grafts differing by major as well as minor histocompatibility antigens occurs at high frequency before (*29*) and during metamorphosis but not afterward (*30, 31*). In *R. pipiens* we have also shown that tolerance to self or to allogeneic eye implants in embryonically enucleated tadpoles frequently occurs (*32*). Thus the high incidence of tumors in premetamorphic and metamorphosing *R. pipiens* may be due to an enhanced capacity to become tolerant to TSTA during this developmental period. As a more formal statement of this hypothesis, virus-inoculated and immunocompetent frogs may have a high incidence of tumors because they become tolerant to TSTA, whereas tx frogs have a high incidence of tumors because they are unable to develop cytotoxic effector cells.

This hypothetical explanation of the data allows several predictions. One might predict that frogs with latent virus, due to embryonic infection, would develop some tumors in larval or perimetamorphic life and then few tumors in postmetamorphic life (until old age interfered with immune competence). A long-term study documenting tumor incidence at regular intervals over several years in embryonically infected frogs has yet to be done, but records of tumor incidence in field-collected and laboratory-held frogs suggest that among adults, tumors are never observed in young frogs but occur frequently in large and presumably older animals (*12, 33*). Tumors developing in premetamorphic tadpoles would presumably result in early death of these frogs.

Our hypothesis would also predict that adult frogs with latent virus would develop more tumors if they were experimentally made tolerant to tumor antigens. Perhaps this may explain the increased incidence of primary tumors in laboratory-held frogs that have been implanted with allogenic Lucké tumor in the anterior eye chamber [(*34*); Rollins-Smith L: Unpublished observations]. Recently, this site has been demonstrated to be a favorable route for induction of tolerance to alloantigens (*35*).

Alternative explanations for our data must include the possibilities that the Lucké tumor is not immunogenic and/or that immune surveillance is irrelevant to tumor survival (*36, 37*). The argument had been made that most tumors begin as small clones and that the early response to a small inoculum of immunogenic cells may lead to stimulation of tumor growth rather than to rejection (*36*). If an early thymic-dependent immune response to a small Lucké tumor is important for tumor promotion, we should have observed a decreased incidence of primary kidney tumors in tx frogs. In fact, the incidence of tumors was the same in normal frogs and tx, virus-infected frogs (tables 1, 2). Mechanisms other than T-cell cytotoxicity, such as natural killer cells or activated macrophages, may be important in the regulation of tumor growth. Little is known about the existence or effectiveness of these cellular effector mechanisms in frogs. Our study addresses only the question of whether T-cell-dependent mechanisms are effective in preventing tumor development; apparently, in these young frogs they are not.

In summary, no increased or decreased incidence of tumors in virus-infected tadpoles was observed as a function of thymectomy. We favor the hypothesis that in postmetamorphic frogs, cytotoxic T-cells, specific for virus-associated tumor antigens, may regulate the development of tumors. As yet, the existence of cytotoxic T-cells specific for Lucké tumor antigens has not been demonstrated. We suggest that tumors may develop at high frequency in normal and tx tadpoles because neither can generate cytotoxic T-cells directed at tumor-specific antigens. The tx frog lacks the thymus-derived progenitors necessary for cytotoxic responses, whereas the normal frog may have very active suppressor mechanisms that prevent their emergence.

Studies on the Antitumor Activities of Pyrimidinone-Interferon Inducers. I. Effect Against Artificial and Spontaneous Lung Metastases of Murine Tumors [1, 2, 3]

Luka Milas, [4] Evan M. Hersh, [5] Dale A. Stringfellow, [6] *and* Nancy Hunter [4, 7]

ABSTRACT—Since pyrimidinone compounds induce interferon production in several animal species and have potent antivirus activities, it appeared important to determine whether these compounds could also induce antitumor activities in their recipients. Pyrimidinone compounds 2-amino-5-bromo-6-methyl-4-pyrimidinone (ABMP), 2-amino-5-bromo-6-phenyl-4-pyrimidinone (ABPP), and 2-amino-5-iodo-6-phenyl-4-pyrimidinone (AIPP) were studied for their activities against artificial lung metastases of the weakly immunogenic spontaneous fibrosarcoma NFSa, the moderately immunogenic spontaneous mammary carcinoma MCa-K, and the strongly immunogenic 3-methylcholanthrene-induced fibrosarcoma FSa syngeneic to inbred C3Hf/Kam mice. In addition, the therapeutic efficacy of ABPP and AIPP was also determined against spontaneous lung metastases of NFSa. ABPP and AIPP given ip at 250 mg/kg for 2 or 3 consecutive days before or after iv inoculation of NFSa, FSa, or MCa-K cells greatly reduced the number of tumor nodules developed in the lungs. ABMP, however, was considerably less effective. ABPP and AIPP were also effective in therapy of spontaneous lung metastases of NFSa, especially when these compounds were given before surgical removal of the primary tumor. Neither ABPP nor AIPP was effective against tumor nodules growing in whole-body irradiated (WBI) mice, but both protected mice against enhancement of lung metastasis formation induced by exposure to whole-body irradiation. ABPP was more effective than AIPP in inducing production of interferon in normal mice. When treated with ABPP, WBI mice, however, were unable to produce interferon. These results show that 6-phenyl-pyrimidinone compounds induce strong antitumor activities in mice, which correlated with neither tumor immunogenicity nor the ability of these agents to induce interferon, but which depended on the immune status of the tumor host.—JNCI 1982; 68:139–145.

Since their discovery in 1957 (*1*), interferons have been known for their antivirus properties. Recently, interferons also have become known for their antitumor activities, and these effects have been demonstrated against many experimental tumors and against several human tumors, including osteosarcoma, breast carcinoma, and tumors of the lymphohematopoietic system (*2*). Biologic activities of interferons are many, such as inhibition of virus replication, inhibition of cell proliferation, and modulation of the immune response, and they all are likely to participate in the exertion of the interferon-induced antitumor effect (*3*). Tumor cells treated with interferons have exhibited a reduced growth in vitro and a reduced potential to form tumors upon transplantation into animals (*3*). By modulating many immune reactions (*2*), interferons can modulate or initiate antitumor resistance mechanisms. They have enhanced specific lymphocyte cytotoxicity against tumor cells (*4*), activated macrophages (*5*), and augmented activity of NK and killer cells (*6*).

There are two approaches to interferon tumor therapy: *a*) administration of exogenous interferon and *b*) administration of interferon inducers to stimulate host cells to produce interferon. Since the production of interferons is limited and costly and their application is restricted by their "species-specific" activity, there is an increasing interest in the identification and development of compounds that could be used for stimulating host cells to produce their own interferons. A wide variety of natural and synthetic agents, including bacteria and their product(s), a double-stranded polyribonucleic acid (polyinosinic-polycytidylic acid), and pyran copolymer, are known for their ability to induce interferons (*3*). More recently, several pyrimidinone compounds have been identified as potent interferon inducers in several animal species and in cultured human tissues (*7, 8*). These compounds exert strong antivirus activities and modulate different immunologic reactions (*7*). Also, it was recently reported that pyrimidinone compounds can restrict the growth of B16 melanoma cells transplanted into the peritoneal

cavities of mice (*8*). These observations suggest that pyrimidinones may be effective in the treatment of malignant tumors, and further experiments on the antitumor effect of pyrimidinone compounds were warranted.

Here we report studies that show that two 6-phenyl pyrimidinones, ABPP and AIPP, induce antitumor activity against pulmonary tumor growths of 3 murine tumors that vary in their immunogenicity and metastatic properties.

MATERIALS AND METHODS

Mice.—Inbred C3Hf/Kam mice of both sexes that had been bred and maintained in the specific-pathogen-free mouse colony of the Department of Experimental Radiotherapy, The University of Texas System Cancer Center, M. D. Anderson Hospital and Tumor Institute, were used. They were 11-14 weeks old at the beginning of the experiments. Within each experiment, the mice were of the same sex and were housed 4-7/cage.

Tumors.—Experiments were performed with 3 transplantable tumors, all syngeneic to C3Hf/Kam mice: spontaneous fibrosarcoma NFSa, 3-methylcholanthrene-induced fibrosarcoma FSa, and spontaneous mammary carcinoma MCa-K. These tumors vary in immunogenicity and metastatic capacity. Most experiments were performed with NFSa, which is a poorly immunogenic tumor as determined by the ability of specifically sensitized mice to influence the take of NFSa cells injected either iv or sc (*9*). Most mice bearing this tumor in the leg develop lung metastases after amputation of legs bearing tumors of approximately 10 mm in diameter (*9*). When used in these experiments, NFSa was in isotransplant generation 12.

FSa is a relatively strongly immunogenic tumor as determined by the same methods used for the estimation of the immunogenicity of NFSa (*10, 11*). A large proportion of mice dying of subcutaneous FSa have metastases in the lungs (*12*). However, mice rarely develop metastases if the primary tumor is removed (*13*). When used in this study, this tumor was in isotransplant generation 6.

The MCa-K tumor is moderately immunogenic as determined by the lung colony assay (*14*). This tumor is, however, of a highly metastasizing propensity: Most animals whose tumors of about 10 mm in diameter are surgically removed develop numerous pulmonary metastases in the lungs (*15*). In these experiments we used isotransplants of generation 7.

Single cell suspensions from fibrosarcomas were prepared by trypsin digestion of nonnecrotic tumor tissue (*11*). Viability of the cells was more than 95% as assessed by trypan blue dye exclusion and phase-contrast microscopy. Single cell suspensions of cells from MCa-K were prepared by a mechanical method (*14*). The viability of cells was approximately 60%.

All experiments, with the exception of the spontaneous metastasis experiment, were performed with the use of the lung colony assay. To produce artificial pulmonary metastases, we suspended 10^5-2.5×10^5 NFSa cells, 2×10^5 FSa cells, or 2×10^5 MCa-K cells in 0.5 ml Hsu's medium and injected these cells iv into groups of 6-10 mice. Fourteen days after inoculation of NFSa and FSa cells and 28 days after inoculation of MCa-K cells, the mice were killed, their lungs removed, and the lung lobes separated and fixed in Bouin's solution. Colonies of tumor cells (metastases) appeared as white, round nodules on the surface of the yellowish lung and were counted with the naked eye.

Studies of spontaneous metastases involved only NFSa. Mice were given injections of 5×10^5 cells in muscles of the right thigh. The resulting tumors were removed by surgery (*15*) when they had grown to about 12 mm in diameter, and 24 days later the mice were killed and their lungs inspected for the presence of metastases as described above.

Pyrimidinone compounds.—Three pyrimidinone compounds were used: ABPP, ABMP, and AIPP, synthesized by Dr. W. Wierenga and Dr. H. I. Skulnick (The Upjohn Co.). The first two compounds were reported to be potent interferon inducers, and the third was a weak interferon inducer (*7*). The compounds were administered ip in 0.3 ml of 1% carboxymethyl cellulose sodium (vehicle). Because of their poor solubility, these compounds were ground together with vehicle in a tissue grinder to achieve a uniform suspension. In most experiments the dose per injection was 250 mg/kg body weight given in two to six injections. In one experiment a single dose of ABPP and AIPP ranging between 62.5 and 1,000 mg/kg was used.

Interferon assays.—Interferon levels were determined in the sera and in 10% supernatants of homogenized spleen, thymus, and lung from mice treated with ABPP or AIPP 6 or 24 hours earlier. Each group consisted of 4 mice. To obtain 10% supernatants, we weighed and mixed the above tissues with Eagle's minimum essential medium in a 1:9 ratio. Each sample was homogenized with a Polytron tissue homogenizer and centrifuged at 2,200 rpm for 20 minutes. The supernatants were removed and refrigerated at −11°C. Serum was prepared by a method described elsewhere (*11*). A standard vesicular stomatitis plaque-reduction assay was performed on murine L929 cells (*7*). To standardize results, we included the international murine interferon standard (G002-904-511), which had a mean titer of 6,200 U/ml compared with its accepted titer of 6,800 U/ml.

WBI.—Mice were exposed to 650 rad WBI with gamma rays. During irradiation from a single-source ^{137}Cs irradiator with a dose rate of 238 rad/minute, groups of 5 mice without anesthesia were restrained in Lucite containers.

Statistical analysis.—The results were evaluated by the nonparametric Mann-Whitney *U* test or by the chi-square test. Differences between the groups were considered significant if the *P*-value of comparison was 0.05 or smaller.

RESULTS

Effect of ABPP, AIPP, and ABMP on artificial lung metastases of NFSa, FSa, and MCa-K.—Mice were given injections iv of 2.5×10^5 NFSa, 2×10^5 FSa, or 2×10^5 MCa-K cells. They were also treated with ABPP, AIPP, or ABMP given ip once a day for 2 or 3 consecutive days before, after, or before and after tumor cell injection. The number of NFSa and FSa tumor nodules was determined at day 14, and the number of MCa-K tumor nodules was determined at day 28 following tumor cell injection (table 1). If injected into mice before tumor cell injection, ABPP and AIPP were effective against all 3 tumors, as shown by a great reduction in the number of metastases. When administed after tumor cell injection, these drugs were effective against NFSa and FSa but not against MCa-K tumor nodules. This activity against NFSa and FSa was less profound than that produced by the drugs given prior to tumor cell injection. Also, two injections of ABPP and AIPP given at days 2 and 7 after injection of NFSa cells caused no reduction in the number of lung colonies. The activity of ABMP was investigated against FSa and NFSa. The number of nodules of FSa was reduced only if ABMP was given before tumor cells. No antitumor activity of ABMP was observed against NFSa; in contrast, certain schedules of ABMP administration even enhanced formation of metastases. However, treatment with ABMP was toxic, because 9 of 35 mice died within 1-9 days after treatment with ABMP. Because of its toxicity and lack of appreciable antitumor activity, ABMP was not used in further experiments.

Since none of the pyrimidinone compounds were effective when given at days 2 and 7 after tumor cell injection, it was important to determine whether the activities of these compounds depend on the dose delivered to mice. Mice received injections iv of 2×10^5 NFSa cells, and 2 days later they received injections ip of ABPP or AIPP in doses ranging from 62.5 to 1,000 mg/kg body weight. The number of lung metastases was determined 14 days after tumor cell injection and is presented in table 2. Single doses of ABPP and AIPP, up to 250 mg/kg, did not significantly reduce the number of colonies. Higher doses, however, did.

Effect of ABPP and AIPP against spontaneous metastases of NFSa.—A high percentage of mice having NFSa tumors in the leg develop metastases in the lungs (*9, 16*). Using this tumor, we investigated whether ABPP and AIPP produce an antimetastatic effect. Primary tumors were induced by injections of 5×10^5 NFSa cells into muscles of the right thighs of mice. Thirteen days later when tumors grew to about 12 mm in diameter, they were surgically removed. Groups of mice received 250 mg ABPP or AIPP/kg ip every day for 2 or 4 days within 5 days prior to surgery or two, four, or six injections of these compounds at different schedules within 14 days after surgery (table 3). Twenty-four days after primary tumors had been removed, mice were killed and their lungs were inspected for the presence of metastases. Of 12 mice, 10 (83%) treated by surgery alone had metastases in the lungs. ABPP and AIPP reduced the incidence of metastases to 39% (30/77) and to 34% (25/73), respectively. Preoperative application of ABPP and AIPP was more effective than postoperative application. Nine percent of the

[a] ABPP or AIPP was injected ip into mice that received iv injections of 2×10^5 NFSa cells 2 days earlier. The No. of tumor nodules in the lung was determined 14 days after iv injection of tumor cells.

[b] Values are means ± SE. *Numbers in parentheses* are *P*-values determined by the Mann-Whitney *U* test. NS=not significant.

mice (3/35) developed metastases if ABPP was given prior to surgery, and 64% of the mice (27/42) had metastases if ABPP was given postoperatively. The incidence of metastases was 17% (5/30) and 47% (20/43) in mice that received AIPP preoperatively and postoperatively, respectively.

Antitumor effect of ABPP and AIPP in WBI mice.—In this experiment we tested whether ABPP and AIPP can exert antitumor activity in immunosuppressed mice. Mice were exposed to 650 rad of gamma rays, and 1 day later they were given injections of 10^5 NFSa cells. ABPP or AIPP was given at days 3 and 2 before or at 3 and 4 days after WBI. The number of lung colonies was determined 14 days after tumor cell injection (table 4). Radiation alone increased the number of lung metastases from 15.0±2.5 in normal mice to 92.0±12.8. Neither ABPP nor AIPP elicited antitumor responses in WBI mice by a detectable reduction in the number of lung colonies. However, when given before radiation, these compounds were able to reduce the metastasis-promoting effect of WBI.

Production of interferon in normal and WBI mice treated with ABPP and AIPP.—The ability of normal and WBI mice to produce interferon following treatment with ABPP or AIPP was determined. WBI with 650 rad was delivered 2 days before treatment of mice with ABPP. Interferon levels were determined in the serum and in supernatants of spleen, thymus, and lung tissue extracts 6 and 24 hours after a single injection or after two injections of ABPP or AIPP given 1 day apart. Results presented in table 5 show that one and two injections of ABPP induced significant production of interferon in normal mice. Levels of interferon were higher in the serum and thymus than in the spleen and lung. Interferon levels in the serum were higher after one injection than after two injections of ABPP. The levels were high at 6 hours after ABPP injections, but in all tested organs they returned to the normal value in 24 hours. At that time, however, a significant level of interferon was still present in the serum. AIPP induced appreciable amounts of interferon only after two injections, but its activity in this respect was far below that of ABPP. In contrast to the high interferon-producing potency of ABPP in normal mice, ABPP was an inefficient interferon inducer in WBI mice.

DISCUSSION

Our results indicate that all three pyrimidinone compounds are capable of inducing antitumor activity in mice, but the magnitude of their effects varies. ABPP and AIPP are similarly effective and far superior to the activity produced by treatment with ABMP. ABMP was not effective in reducing lung metastases of NFSa, but it reduced the number of lung nodules of FSa only if it was given before iv injection of tumor cells. Therefore, this compound does not seem promising as an immunotherapeutic agent. ABPP and AIPP are more effective when given before rather than after tumor cell injection, a common observation in studies with BRM (*17, 18*). It appears that to achieve appreciable antitumor effect, ABPP or AIPP when given after tumor cells should be given more than one or two times (tables 1, 2). Three injections were quite effective against NFSa and FSa, but they were not effective against MCa-K. Recently, Stringfellow (*8*) reported that

TABLE 3.—*Effect of ABPP and AIPP on spontaneous pulmonary metastases of NFSa in C3Hf/Kam mice*

Treatment with ABPP or AIPP, 250 mg/kg ip[a]	Proportion of mice with metastases at 24 days after amputation of the primary tumor[b]		P^c

[a] On day 0, mice were given injections of 10^5 NFSa cells, and 14 days later they were killed for determination of the No. of tumor nodules in the lung. Mice were irradiated with 650 rad WBI on day −1.

[b] Determined by the Mann-Whitney *U* nonparametric test. NS = not significant.

ABPP, ABMP, and AIPP prolonged the survival of mice bearing B16 melanoma in the peritoneal cavity.

ABPP and AIPP reduced the incidence of spontaneous metastases of NFSa, especially when these compounds were applied to mice before surgical removal of primary tumors. The superiority of preoperative administration over that of postoperative administration is in agreement with our earlier observations of a similar effect produced by treatment with *Corynebacterium parvum* (*15*) and the MVE-2 fraction of pyran copolymer (*16*). The reasons for a better antimetastatic effect of preoperative application of ABPP and AIPP are not clear, but the following may be taken into account. Metastatic foci in the lung are composed of fewer cells at the time of preoperative application than at the time of postoperative application of pyrimidinone interferon inducers, and therefore these foci would be expected to be eliminated more easily by augmented antitumor resistance mechanisms. Also, in the preoperative situation, antitumor resistance mechanisms, initiated or augmented by ABPP or AIPP, most likely act not only against already established metastases but also against tumor cells prior to their establishment in the lung. Recently, Hanna and Fidler (*19*) observed that NK cells were effective in destroying tumor cells within the circulation, but they had only a limited inhibitory effect on established micrometastases. This may also be a major reason for the better prophylactic than therapeutic activities of ABPP and AIPP in experiments with artificial lung metastases. Depression of the immune system caused by surgical trauma may be an additional factor responsible for the less effective antimetastatic effect of postoperative application of ABPP and AIPP. Studies with WBI animals (table 4) showed that immunodepressed animals would be expected to respond to these agents less well than normal animals. BRM-augmented radiocurability of tumors exposed to local tumor irradiation is found to be ex-

TABLE 5.—*Serum and organ interferon levels in C3Hf/Kam mice, normal, WBI, or tumor bearing, after treatment with ABPP or AIPP*

Mice[a]	Hours after treatment with ABPP or AIPP inducers when interferon levels were determined	Interferon levels, U/ml in[b]			
		Serum	Spleen	Thymus	Lung
Normal mice		<10	<10	<10	<10

	24	<10	<10	22	<10

[a] In normal mice ABPP and AIPP were given ip at a dose of 250 mg/kg once or twice with a 1-day interval between two injections. In tumor-bearing mice, 250 mg/kg was given 2 days after iv injection of 2×10^5 NFSa cells. WBI was achieved by 650 rad 2 days before treatment with ABPP.

[b] Determination of interferon levels described in the text. A level of <10 U/ml is the lowest detectable level, since samples were not assayed at dilutions lower than 1:10.

pressed more profoundly if BRM are applied before rather than after tumor radiation (*12, 20*). Therefore, the present observations (table 3) with those already reported (*12, 15, 16, 20*) suggest that it may be justifiable for the clinician to consider applying immunotherapeutic agents before the primary tumor is surgically removed or exposed to radiotherapy.

Three aspects of antitumor activity of pyrimidinone compounds were investigated in this study: *a*) efficacy against tumors that vary in their immunogenicity; *b*) dependency of antitumor activity on the immunocompetence of mice; and *c*) dependency of antitumor activity on the interferon-inducing potency of these agents.

To induce the immunosuppression state, we exposed mice to sublethal WBI. This procedure commonly facilitates tumor take by both suppression of antitumor resistance responses (*21*) and through nonimmunologic effects (*22*). WBI increased the number of lung colonies in the present study, and this increase was not affected by ABPP or AIPP when given 3 days following radiation. Also, in contrast to normal mice, WBI mice did not produce interferon when treated with ABPP. Stringfellow et al. (*7*) reported earlier that production of interferon by mice exposed to pyrimidinone compounds depended on the presence of radiosensitive but not cortisone-sensitive cells. It follows, therefore, that WBI compromised the system responsible for mounting antitumor responses. As mentioned in the introduction, pyrimidinone compounds activate macrophages and potentiate NK cell activity, and these cells are considered to play an important role in tumor rejection (*17, 18, 23*). It is likely, then, that antitumor activity observed in this study may be a result of such activity of pyrimidinone compounds. It is known that the antitumor activities of activated macrophages are resistant to ionizing radiation (*21, 24, 25*), but activation of macrophages is difficult to achieve in mice exposed to WBI. This fact may explain why treatment of mice with ABPP or AIPP can protect to a significant degree against enhancement of lung metastases produced by WBI delivered to mice following treatment with pyrimidinone compounds (table 4). The effect of ionizing radiation on NK cell activity is less defined than the effect of radiation on macrophages. Spleen cells derived from mice exposed to 1,100 rad (*26*) or 100-900 rad (*27*) WBI 1 day earlier exhibited no decrease in NK cell cytotoxicity. Hochman et al. (*28*) observed that the NK activity of spleen cells from mice given 700 rad of whole-body gamma rays persisted at the level of the NK activity of spleen cells from unirradiated mice for 12 days after radiation. Thereafter, the activity of NK cells temporarily declined, and the authors' conclusion was that NK progenitor cells, but not mature NK cells, are sensitive to ionizing radiation. More recently, Djeu et al. (*29*) reported that X-irradiation with doses of 300-1,200 rad inhibited NK cells when the activity of these cells was assayed 1 day after radiation. The extent of radiosensitivity of NK cells greatly depended on the mouse strain used. However, in vitro irradiation of spleen cells did not influence the cytotoxicity of NK cells. Also, an interferon inducer, polyinosinic-polycytidylic acid, was able to augment NK activity in mice exposed to 300-900 rad WBI 4-6 hours earlier. These observations led Djeu et al. (*29*) to conclude that precursor NK cells and lytic activity of NK cells exposed in vitro to radiation are radioresistant and that only active NK cells are radiosensitive following exposure of animals to radiation. Therefore, if NK cells participated in the antitumor resistance produced by ABPP and AIPP, the inability of these agents to mount an antitumor response in WBI mice might be explained on the basis that NK cells in our mice were sensitive to radiation. If, however, NK cells of our mice were not sensitive to radiation, their activity could not become augmented in WBI mice simply because radiation abrogated the ability of mice to produce interferon in response to treatment with ABPP and AIPP (table 5), and therefore a factor (interferon) that was needed for augmentation of NK cells was lacking.

Pyrimidinone compounds induce production of interferon (table 5), which can inhibit proliferation of tumor cells both by direct action on tumor cells and by stimulation of the antitumor responses of the host (*2*). Our data demonstrate the lack of correlation between the antitumor activities of pyrimidinone compounds and their ability to induce production of interferon. ABPP is a more potent interferon inducer than AIPP, yet both exhibit antitumor activities of similar magnitudes. Stringfellow et al. (*7*) reported that ABMP is as effective as ABPP in interferon-inducing capacity. However, ABMP is the least effective of the three pyrimidinone compounds tested in reducing the number of tumor nodules in the lung. The kinetics of interferon production are not the same for ABPP and AIPP. Whereas only one injection of ABPP is sufficient to produce high serum levels of interferon, two injections of AIPP are required to achieve any appreciable level of interferon in the serum. The relevance of this phenomenon to the antitumor activities of ABPP and AIPP remains to be established. We are presently performing experiments to establish whether sera from ABPP-treated and AIPP-treated animals, which contain different amounts of interferon, differ in their ability to transfer antimetastatic activity to normal mice.

It also appears that the activities of ABPP and AIPP did not depend on tumor immunogenicity. Both poorly and highly immunogenic fibrosarcomas were similarly affected, whereas moderately immunogenic MCa-K was less sensitive. If antitumor resistance mechanisms were involved in the activities of ABPP and AIPP, our observations suggest that they are likely to be mainly immunologically nonspecific.

Using the same animal models, we recently reported that the MVE-2 fraction of pyran copolymer, which is also a potent inducer of interferon, had an antitumor activity of similar magnitude to the antitumor activities reported here for pyrimidinones (*16*). For example, when given preoperatively, MVE-2 reduced the incidence of NFSa spontaneous metastases by 93%, and when given postoperatively, by 27%. Data presented in table 3 show that ABPP and AIPP when given before surgery of the primary tumor reduced spontaneous metastases of the same tumor by 89 and 80%, respectively, and when given after surgery, by 25 and 43%, respectively. However, the number of injections, dose, and time of injection in relation to the surgical treatment were different in studies with MVE-2 and in the present studies with ABPP and AIPP.

In conclusion, our results provide information that pyrimidinone compounds ABPP and AIPP exert an appreciable activity against both artificial and spontaneous tumor metastases in mice. The antitumor effect is dose-responsive. The activity was achieved in normal mice but not in WBI mice, was independent of tumor immunogenicity, and did not correlate with the potency of these compounds to induce production of interferon.

Rat Mammary Tumor Classification: Notes on Comparative Aspects[1, 2]

Dymitr Komitowski,[3] Bernard Sass,[4, 5] *and* Walter Laub[3]

ABSTRACT—Mammary tumors (170 spontaneous and 1,613 induced with 7,12-dimethylbenz[*a*]anthracene) in inbred SD rats were classified histologically. The neoplasms were divided into three main categories: fibroepithelial, epithelial, and connective tissue. In the fibroepithelial category, compound tumors showing a wide range of histologic structures with variation in the arrangement of both epithelial and connective tissue elements that differ among lobules occurred in 44 (25.9%) spontaneous and 1,027 (63.7%) induced neoplasms, whereas fibroadenomas occurred in 41 (24.1%) untreated and 175 (10.9%) treated rats. Uncommon fissured tumors were found in 1 (0.7%) untreated and 6 (0.4%) treated animals, whereas carcinosarcomas were found in only 10 untreated animals. In the epithelial category, tubular adenomas occurred in 48 (28.2%) untreated and 164 (10.2%) treated animals. Cystadenomas, duct papillomas, intraductal carcinomas, and anaplastic carcinomas were found less frequently. Adenoacanthomas occurred in only 12 (0.8%) of the treated animals. Among tumors with a fibrous component only, fibromas occurred in 22 (13%) untreated and 97 (6.0%) treated animals. Fibrosarcomas were less frequent, occurring in 4 untreated (2.4%) and 54 (3.4%) treated animals.—JNCI 1982; 68:147–156.

Numerous attempts have been made to classify rat mammary tumors since the earliest report of their occurrence by McCoy (*1*). Bullock and colleagues (*2–4*) published early descriptions and attempts at classification of spontaneous mammary neoplasms. More recently, Thompson et al. (*5*), Crain (*6*), and Burek and Hollander (*7*) studied incidence patterns of spontaneously occurring neoplasms, including mammary neoplasms, in various rat strains and attempted to classify these neoplasms. The morphology of chemically induced neoplasms has been studied by Dunning et al. (*8*), Young et al. (*9*), Middleton (*10*), and Archer and Orlando (*11*). As yet, no one classification has been generally accepted because there are great variations in morphology not only among these tumors but also among components of a single tumor. Mammary tumors of rats also differ morphologically and biologically from those of other animals and humans, although histologically there is some superficial resemblance. The unique morphology of these tumors must be considered when one is classifying them for the purposes of experimental pathology. Uniform pathologic nomenclature and clearly defined criteria for classification are lacking.

Spontaneous and induced neoplasms of rat mammary glands have been used as experimental models for human breast tumors, particularly in studies of chemotherapy of such tumors. The implication is that both types of neoplasms are morphologically and biologically similar. To analyze similarities between morphologic forms of mammary gland tumors in rats and those in humans, one must introduce appropriate classifications. One report provides a classification of rat mammary tumors based on histologic criteria and terminology corresponding to those used for human breast neoplasms (*12*). Our classification of rat mammary tumors is based on two general, albeit opposite, concepts: 1) Unique histologic forms characteristic for the rat should be distinguished; 2) terminology and criteria for typing should permit comparison between tumors of humans and those of other animals.

A large number of rat mammary tumors, accessed at the Division of Histodiagnostic and Pathomorphological Documentation, the German Cancer Research Center, were used for this study.

MATERIALS AND METHODS

Tumors.—More than 2,500 tumors of the mammary gland obtained from different rat strains in our collection served as a basis for this study. Of the total, 1,783 mammary tumors (170 spontaneous and 1,613 induced) from female inbred SD rats were examined by stepwise serial sectioning of several slices from each tumor. The tumors were obtained from 1,494 rats (552 control and 942 treated). The rats with spontaneous tumors comprised 31% of the control animals. Most of the animals (80% control and 60% treated) developed only one tumor. Eighty induced tumors were obtained from in-house experiments, conducted by the senior author, in which 80 conventionally reared, 6-month-old female inbred SD rats obtained from in-house stock were used. The rats were housed in pairs in plastic cages and were fed a mixed diet (Altromin 1324) and received water ad libitum. The rats were then divided into groups of 20 each and were given 7,12-dimethylbenz[*a*]anthracene (The Upjohn Co., Kalamazoo, Mich.) either by iv injection at 25 mg/kg, by sc injection at 1 mg/kg, or by gavage at 10 mg/kg.

Histologic examination.—Animals were killed by cervical dislocation, and a complete necropsy was

Our classification of rat mammary tumors is based on two general, albeit opposite, concepts: 1) Unique histologic forms characteristic for the rat should be distinguished; 2) terminology and criteria for typing should permit comparison between tumors of humans and those of other animals.

A large number of rat mammary tumors, accessed at the Division of Histodiagnostic and Pathomorphological Documentation, the German Cancer Research Center, were used for this study.

MATERIALS AND METHODS

Tumors.—More than 2,500 tumors of the mammary gland obtained from different rat strains in our collection served as a basis for this study. Of the total, 1,783 mammary tumors (170 spontaneous and 1,613 induced) from female inbred SD rats were examined by stepwise serial sectioning of several slices from each tumor. The tumors were obtained from 1,494 rats (552 control and 942 treated). The rats with spontaneous tumors comprised 31% of the control animals. Most of the animals (80% control and 60% treated) developed only one tumor. Eighty induced tumors were obtained from in-house experiments, conducted by the senior author, in which 80 conventionally reared, 6-month-old female inbred SD rats obtained from in-house stock were used. The rats were housed in pairs in plastic cages and were fed a mixed diet (Altromin 1324) and received water ad libitum. The rats were then divided into groups of 20 each and were given 7,12-dimethylbenz[*a*]anthracene (The Upjohn Co., Kalamazoo, Mich.) either by iv injection at 25 mg/kg, by sc injection at 1 mg/kg, or by gavage at 10 mg/kg.

Histologic examination.—Animals were killed by cervical dislocation, and a complete necropsy was

performed. All mammary tumors were removed and cut into slices of approximately 5×10 mm. In addition to slices of mammary tumors and those from organs with gross evidence of metastasis, slices of liver, lung, spleen, kidney, adrenal gland, and brain were collected. The tissue samples were fixed in 10% neutral buffered Formalin (24 hr at 4°C) and embedded in Paraplast; they were sectioned at 4 µm and routinely stained with hematoxylin and eosin. Special stains were used. Van Giesson and Masson-Goldner's stains were used for collagen fibers. Orcein was used for elastic fibers. The impregnation technique of Gomori was used for the argyrophilic fibers, and a periodic acid-Schiff reaction, according to the method of McManus (*13*), was used for staining neutral mucopolysaccharides and basement membrane.

RESULTS

The histologic appearance of rat mammary tumors is related to the extent and distribution of the main structural components—fibrous stroma and duct epithelium. According to these criteria, the most prevalent types were fibroepithelial tumors, epithelial tumors, and fibrous tumors.

Fibroepithelial tumors assume a lobular growth pattern and are characterized by outgrowth of both the duct epithelium and the intralobular connective tissue.

The epithelial tumors are neoplasms with accentuated growth of the epithelium. Fibrous stroma, often abundant, appears as bands of dense collagen bundles between the compactly arranged epithelial formations.

Fibrous tumors have the growth pattern of connective tissue neoplasms. Structures resembling normal or atrophic ducts occasionally can be seen between the loosely textured connective tissue fibers.

The histologic criteria used to determine in which main groups individual tumor forms belonged were: uniformity of growth pattern, relationship between stroma and epithelium, gland and tubule formation, cell type, regularity of nuclei, mitosis, and invasiveness.

The following is a proposed classification of rat mammary tumors:

I. Fibroepithelial tumors
  A. Fibroadenomas
    1. Tubular or acinar
    2. Sclerosing
    3. Proliferating
    4. Fissured
  B. Compound tumors
  C. Carcinosarcomas
  D. Lobular carcinomas
II. Epithelial tumors
  A. Tubular (simple) adenomas
  B. Cystadenomas
  C. Anaplastic adenocarcinomas
    1. Small cell type
    2. Glomerate type
  D. Squamous cell tumors
    1. Squamous cell carcinomas
    2. Adenoacanthomas
III. Tumors composed wholly of fibrous tissue
  A. Fibromas
  B. Fibrosarcomas

The distribution of different histologic types among the 1,783 mammary tumors is shown in table 1. The incidence of spontaneous and induced tumors is given separately. Table 1 also presents the number and percent incidence of metastases in the different groups. All metastases were localized in the lungs and were observed by gross examination and confirmed histologically.

Fibroepithelial Tumors

Fibroepithelial tumors are the most frequently occurring type of mammary gland neoplasia in rats.

TABLE 1.—*Incidence of the different types of mammary tumors registered in the Division of Histodiagnostic and Pathomorphological Documentation, German Cancer Research Center*

Tumor classification	Spontaneous tumors		Induced tumors		Total tumors		Metastases	
	No.	Percent	No.	Percent	No.	Percent	No.	Percent
I. Fibroepithelial tumors								
A. Fibroadenomas	41	24.1	175	10.9	216	12.1	0

	170		1,613		1,783		21	

Proliferation of both tubular epithelium and fibrous stroma and a lobular pattern of growth are distinguishing features of these tumors. Histologic appearance is characterized by more or less regular distribution of the epithelial structures throughout the excessive connective tissue stroma. Epithelial and fibrous components vary greatly in their proportions, structural relationships, and degree of differentiation in different tumors. On the basis of these criteria and the biologic features of tumors, different morphologic forms may be distinguished: fibroadenomas, compound tumors, carcinosarcomas, and lobular carcinomas.

Fibroadenomas

Fibroadenomas are the second most common spontaneous neoplasm of the rat mammary gland. Histologically, they reveal a characteristic pattern created by the appearance of tubules lined by a single layer of epithelium in an abundant fibrous stroma showing peritubular arrangement of the fibers. The epithelial and fibrous components of fibroadenomas vary in their morphologic features. Accordingly, four subtypes of fibroadenomas can be distinguished: tubular (acinar), sclerosing, proliferating, and fissured. Foulds (*14*) has reviewed the morphology of primary and transplanted fibroadenomas. These tumors are transplantable, although they grow very slowly. When these tumors are transplanted into young female rats, epithelial elements predominate, whereas in older females lipid or cartilage is abundant. If these tumors are transplanted into male rats, fibrosarcoma elements predominate. Thus fibroadenomas are hormone-dependent tumors.

Acinar fibroadenomas (fig. 4) are neoplasias in which epithelium is organized in single, well-formed acini separated by concentrically arranged loose-textured connective tissue fibers. The epithelium lining the acini consists of two layers and appears to be identical to that of normal mammary glands. The epithelial cells may contain cytoplasmic vacuoles as a result of secretory activity.

Sclerosing fibroadenomas (fig. 5) reveal extensive fibrosis. Stromal connective tissue is dense with abundant collagen fibers and acellular and hyalinized areas. These tumors often contain an increased number of mast cells. The duct epithelium is flat, sometimes apparently atrophic.

Proliferating fibroadenomas (fig. 6) exhibit morphologic evidence of an increase in growth potency of epithelium lining tubular structures. In comparison with other subtypes of fibroadenomas, the neoplastic tubular structures are elongated and irregular. The epithelium consisting of columnar or cuboidal cells with prominent nuclei is multilayered with focal budlike outgrowths.

Fissured fibroadenomas (fig. 7) are composed of epithelium arranged in slitlike gland spaces and of fibrous stroma forming polypoid structures. The epithelium varies in its appearance from one region to another. It may be found in one layer or multiple layers or even may be absent in some places. The bulky lobulated masses of the stroma exhibit cysts, myxomatous changes, and highly cellular and hyalinized areas.

Compound Tumors

Compound tumors are distinctive types of neoplasms of the rat mammary gland and the most frequently observed experimentally induced mammary tumors. These tumors have a lobular growth pattern and complex morphology in which a wide range of structures can be recognized—from well-organized tubules to cystic and pseudopapillary formations to solid, highly cellular foci. The general histologic pattern is tubulopapillary and is obviously a result of ingrowth of glandular epithelium into the dilated cystlike ducts (fig. 1).

Proliferating epithelium forms secondary structures of glandular, cribriform, lacelike, or arborescent appearance that fill the cystic spaces (fig. 2). Characteristically, the epithelium lining these structures is arranged in layers consisting of two types of cells: *a*) intensely eosinophilic columnar cells with dense nuclei of the innermost layer delineating the lumen and *b*) pale, polygonal, or round cells with lightly stained nuclei situated in the more peripheral layers (fig. 3). The cells of both types and especially those from peripheral layers contain many cytoplasmic vacuoles. The highly cellular solid foci are comprised of pale cells. The fibrous stroma shows differences in the cellularity and density of the fibers in different areas. Typical are the myxomatous changes. The compound tumors may be well differentiated and circumscribed or anaplastic and infiltrating.

No direct relationship between the degree of histologic differentiation and infiltrating growth or even metastases can be found. Therefore, the designation of benign or malignant is arbitrary. Compound tumors must be clearly distinguished from different subtypes of fibroadenomas and from the lobular carcinoma. Histologic criteria indicative of compound tumors are lobular growth pattern, variability of the histologic structure with areas of different histomorphology within the same tumor (including tubular, papillary, or solid formations), two types of epithelium, and myxomatous changes in the stroma.

Carcinosarcomas

Carcinosarcomas (fig. 9) are rare tumors of the rat mammary gland. In our collection we found few tumors (0.6% of all tumors) with apparently concomitant malignant growth of tubular epithelium and connective tissue. These tumors invade neighboring tissue and occasionally metastasize.

Lobular Carcinomas

Although most fibroepithelial mammary tumors of rats may show lobular patterns of growth, we believe that the lobular carcinoma (fig. 8) is a distinct tumor type. Lobular carcinoma apparently arises from the proliferating epithelium of the terminal ducts that fills and distends their lumina. The duct epithelium forms glandular or cribriform structures separated by a delicate fibrous stroma. The secondary lumina of these structures often contain eosinophilic secretory material. The intralobular stroma often contains a significant number of mast cells usually appearing in groups. Frequently, the stroma reveals myxomatous changes. In contrast, the perilobular stroma separating the individual lobules is composed of broad connective tissue bundles infiltrated diffusely by lymphocytes and mast cells.

Distinguishing features of lobular carcinoma are the lobular pattern, the glandular epithelial structures supported by typical connective tissue stroma, and the inconspicuous papillary formations.

Epithelial Tumors

A fibrous component is an integral part of all mammary tumors of rats. There are, however, tumor types that exhibit the basic growth pattern of glandular epithelial neoplasms. The individual tumor types in this group are: tubular (simple) adenomas, cystadenomas, anaplastic adenocarcinomas, and squamous cell tumors.

Tubular (Simple) Adenomas

Tubular adenoma is composed of compactly arranged tubular structures surrounded by delicate connective tissue fibers (fig. 10). The duct epithelium consists of large, pale, vacuolated cells that fill the lumen (fig. 11). The lobules of tumor tissue are surrounded partly by fibrous tissue.

Cystadenomas

Although cyst formation can be encountered in almost all rat mammary tumors, cystadenomas have distinctive histologic features. The tumors have a multicystic pattern with papillary projections that extend into the cystic spaces. The lining epithelium is cuboidal with basophilic cytoplasm and is arranged as fungiform aggregates of cells (fig. 12). Cystadenomas have calcific bodies.

Anaplastic Adenocarcinomas

Anaplastic adenocarcinoma is a common name for highly cellular infiltrating mammary neoplasms. The tumors are composed of pleomorphic cells arranged in various configurations. Large cell carcinomas with alveolar pattern and round cell, diffusely growing tumors can be recognized. Most of the anaplastic adenocarcinomas can be considered as more anaplastic compound tumors. Two histologic types of anaplastic adenocarcinomas of the rat mammary gland require special mention: small cell type and glomerate type.

The small cell type is the most characteristic form of anaplastic adenocarcinoma of the rat mammary gland and consists of small epithelium-like cells usually assembled into alveoli, giving rise to nests of cells or poorly defined glands and sheetlike formations of tumor cells that demonstrate marked loss of polarity (fig. 13). In our studies the small cell adenocarcinoma was the most malignant, on the basis of its ability to metastasize. Glomerate anaplastic adenocarcinomas have structures resembling abortive renal glomeruli and elongated cordlike tubules. The cells are arranged in compact nests or in tortuous ribbons and whorls in which several concentric layers can be recognized (fig. 14). One of these layers consists usually of darker cells having intensely stained nuclei lying close together and lining narrow tubules.

Squamous Cell Tumors

Although different histologic types of rat mammary tumors exhibit varying degrees of squamous metaplasia, pure squamous cell tumors are rare. On the basis of the extent of squamous metaplasia and tubular structure, two histologic forms can be distinguished: squamous cell carcinoma and adenoacanthoma.

Adenoacanthoma (adenosquamous carcinoma) consists of neoplastic epithelial cells arranged as acini and varying degrees of keratin pearl formation (fig. 15). Adenoacanthomas also occur in mice (*15, 16*).

Epithelial pearls were found also in tumors that appeared as anaplastic adenocarcinomas.

Tumors Composed Wholly of Fibrous Tissue

Large areas of fibrous connective tissue can be seen in different rat mammary tumors. In some instances, however, the extent and histologic features of the neoplastic connective tissue can assume the growth pattern of true fibromas (fig. 16) or fibrosarcomas. Characteristics of benign fibrous tumors and some well-differentiated fibrosarcomas of rat mammary gland that distinguish these tumors from fibrosarcomas of other sites are the fine-textured fibers, the tendency to form concentric whorls, and the abundance of mast cells.

DISCUSSION

Mammary tumors of rats reveal features characteristic of this species as compared with mammary gland neoplasms of other animals and humans. Human breast neoplasms are characterized by neoplastic growth of duct epithelium. Three stages of development can be distinguished: intraductal precancerous proliferation, intraductal noninfiltrating carcinomas, and extraductal infiltrating carcinomas.

All known classifications of human breast tumors indicate their genesis from duct epithelium and reflect their specific morphology distinguishing a variety of epithelial neoplasias; however, Wellings et al. (*17*) believe that human breast tumors originate in the terminal ductal-lobular unit. Such classifications, however, are inadequate for fibroepithelial tumors of the rat mammary gland in which both epithelial and fibrous components proliferate. This is also true for the existing classifications of rat mammary tumors based on the classification of human breast tumors. The major morphologic feature of rat mammary tumors differentiating them from human breast tumors is the great diversity of histologic appearances in different regions of one tumor in the rat. These features necessitate the introduction of different terminology for the classification of rat mammary tumors. We propose the term "compound tumors" for lesions that, despite complex morphology, are histologically quite distinct from all other forms of rat mammary tumors. Compound tumors have some features in common with fibroadenomas and are often composed in part of fibroadenomas. Compound tumors differ from fibroadenomas by their basic growth pattern of epithelial and fibrous components. Typical fibroadenomas are defined by the proportion of epithelium and connective tissue stroma and structural relationship. Histologically, they reveal single, epithelium-lined ducts dispersed between abundant stroma showing concentric periductal arrangement of the fibers. The duct epithelium proliferates to form new tubular branches. The epithelial cells lining the ducts, although occasionally exhibiting multilayered arrangements of solid clumps (proliferating and fissured fibroadenomas), resemble those in normal mammary tissue. The compound tumors are characterized by multilayered epithelium with two distinct cell types and by the coexistence of tubular, cystic, papillary, and solid formations. Proportions and structural relationships between the fibrous stroma and epithelium in compound tumors vary greatly and cannot be clearly defined. In contrast to fibroadenomas that are benign and exhibit expansive growth, compound tumors as pathologic entities include both benign and malignant elements. In our study, we observed compound tumors that metastasized but did not have the cell and nuclear pleomorphism indicative of cancer. The designation of fibroadenomas as benign or malignant is contradictory, since these neoplasms grow expansively and are transplantable. In addition, the term "compound tumor" implies neoplastic growths with complex morphology that fail to reveal definite histologic criteria for the differentiation of benign from malignant forms. Our preliminary histochemical and electron microscopic studies suggest that the morphogenesis of the compound tumors is a result of specific interactions between connective tissue stroma, ductular epithelium, and myoepithelial cells (Komitowski D: Unpublished data). The role of myoepithelial cells in the morphogenesis of rat mammary tumors, although postulated (*18, 19*), has not yet been proved. This is true also for mast cells that are a conspicuous cellular element of the connective tissue stroma of different rat mammary neoplasias, such as fibroadenomas, lobular carcinomas, compound tumors, or fibromas. In our studies, the number of the mast cells and the process of desmoplasia in the tumors are correlated. Therefore, mast cells are most prominent in sclerosing fibroadenomas as compared with other forms of fibroadenomas. The occurrence of mast cells in rat fibroadenomas has also been reported by others (*12*) but has not been explained. Because the mammary tumors of rats typically exhibit extensive fibrosis, the question of whether mast cells are a result of, or a possible contributing factor to, fibrosis may be an area for further investigations. Our studies indicate that fibroplasia is a process in which both basic types of connective tissue of rat mammary gland, interlobular and intralobular, evolve differently. Epithelial and fibrous tumor forms show proliferation of interlobular connective tissue, whereas fibroepithelial tumors show proliferation of the intralobular connective tissue. These types of connective tissue differ morphologically and functionally. Because the intralobular connective tissue changes under the influence of hormones, it may be suggested that hormones are important also in the morphogenesis of rat mammary tumors. This influence is also supported by the fact that most tumors show secretory activity.

Lobular carcinomas occur in both humans and rats. The lobular carcinoma of the human breast is a distinctive anatomic entity composed of small cells associated with a poor prognosis. The lobular carcinoma of the rat mammary gland resembles the lobular carcinoma of the human breast only with regard to its overall architecture. In both tumors, the lobular architecture is preserved. Further studies are needed to trace the development of lobular carcinoma in the rat.

Fibroadenoma of the rat mammary gland is the tumor type that most resembles its counterpart in humans, although carcinosarcoma and tubular adenoma are also morphologically similar in the two species.

Some of the neoplasms of the rat mammary gland are histologically similar to those in mice. Mammary tumors of mice have been investigated intensively and have been well characterized histologically. According to Dunn (*15*), these tumors reveal a basic acinar structure. The basic structure of rat mammary tumors is tubulopapillary. In our opinion, only a few histologic forms of these tumors can be compared with those in mice. This is true for cystic adenomas, which assume features similar to so-called "lacelike" or adenocarcinoma type L of mice initially described in strains DD and (C3H × Y)F_1. Corresponding to the fissured tumors of rats is a type Y mammary tumor of mice described in strain C3H-A^{vy} (*16*). As compared with those in rats, fissured tumors in mice show more tubular structures lined by cuboidal epithelium and branching at acute angles. Simple adenomas in rats may be compared with so-called "type C" tumor in mice. However it is unclear whether this type occurs only in old animals, as in the mouse, and whether it is a reaction to an atrophic process in the mammary

Induction of Nasal Tumors in Rats Exposed to Hexamethylphosphoramide by Inhalation[1]

Ki P. Lee, *D.V.M., Ph.D.,*[2] *and* **Henry J. Trochimowicz,** *D.Sc.*[2,3]

ABSTRACT—Charles River-CD Sprague-Dawley rats in 4 equal groups of 240 each were exposed to 4,000, 400, 50, and 0 ppb of hexamethylphosphoramide (HMPA) vapor for 9 to 24 months. In an additional study, 4 equal groups of 200 rats were similarly exposed to 100, 50, 10, and 0 ppb HMPA vapor. Nasal tumors were first detected after approximately 7 months exposure at 4,000 and 400 ppb, after 9 months at 100 ppb, and 12 months at 50 ppb. No HMPA-related lesions were found at 10 ppb. Tumor incidence was 83% at 4,000 ppb exposure, 82% at 400 ppb, 38% at 100 ppb, and 20% at 50 ppb after 24 months of exposure. Most tumors developed from the squamous, respiratory epithelium and nasal gland both of which showed squamous metaplasia or dysplasia in the anterior nasal cavity. Exposure concentrations correlated with tumor induction and latency but not with tumor types. Of a total of 473 nasal tumors, epidermoid carcinoma was predominant (71.9%), followed by adenoid squamous carcinoma (15%), papilloma (8.2%), transitional (respiratory epithelial) carcinoma (1.9%), adenocarcinoma (1.3%), and undifferentiated tumor (1.1%), (mixed) pleomorphic tumor (0.4%), and adenomatous polyp (0.2%). Most tumors developed in the anterior nasal cavity (59.1%), then progressed to the posterior nasal cavity (40.9%). Only 0.4% of the tumors involved the posterior nasal cavity alone. Tumors invaded the nasal bone (47.5%) and brain (1.1%), or metastasized to the lung (1.5%) and cervical lymph nodes (1.1%). Malignancy of the epidermoid carcinoma was correlated to the cellular differentiation and degree of keratinization.—JNCI 1982; 68:157–171.

HMPA has been extensively used as a solvent in research laboratories. It has a wide range of uses in industry as a solvent for polymers, as a polymerization catalyst, as a stabilizer against thermal degradation in polystyrene, as an additive to polyvinyl and polyolefin resins, and as a protective agent against degradation by UV light (*1*, *2*). HMPA was one of the first nonalkylating compounds used for the sterilization of male insects (*3*). Because of its low acute toxicity, chemical stability, and solubility in most polar and nonpolar solvents, it has been tested widely as a chemosterilant for insects and other organisms (*4–6*).

HMPA was reported to induce dominant lethality in male mice (*7*). In contrast, no reproducible dominant lethality was seen in mice by other researchers (*8*). HMPA produced mutagenic effects in fruit flies (*9*), whereas studies of the effects of HMPA on human (*10*) and mouse chromosomes (*11*) showed no chromosomal aberrations. HMPA is known to cause a variety of toxic effects on laboratory animals after oral administration such as kidney damage (*12*), severe bronchopneumonia with bronchiectasis and squamous metaplasia (*13–15*), and testicular atrophy (*16*, *17*). Oral administration of HMPA produced synergistic effects on *Mycoplasma pulmonis* and markedly enhanced the incidence of murine pneumonia and rhinitis (*15*). Since the chronic inhalation toxicity of HMPA was unknown, we conducted a series of experiments to determine the toxic effects and carcinogenic potential of HMPA by inhalation.

MATERIALS AND METHODS

Exposure apparatus.—HMPA was delivered by syringe drive into a stainless steel tube extending through a preheated vapor generating furnace. Vapors from the furnace were carried to a 1-liter flask by houseline air at a rate of approximately 20 liters/minute and diluted to 28 liters of air/minute. The mixture then flowed into a delivery line carrying make-up air for the chamber. Make-up air consisted of a 2- to 5-m^3/minute flow of cooled room air, as a final dilution, to achieve the desired atmospheric concentration in a 5-cubic foot chamber. Chamber air temperature was always maintained below 30°C. To monitor chamber atmospheres for HMPA, a minimum of six samples were taken during each 6-hour exposure. To analyze HMPA levels, 4–40 liters of chamber air was drawn through a midget impinger containing deionized water. The solution from the impinger was diluted to a standard volume and analyzed by a wet chemistry method.

Experimental design.—In experiment I a total of 960 young adult outbred Charles River-CD Sprague-Dawley-derived rats was divided into 8 equal groups of 120 males and 120 females. Group 1 male and group 2 female rats were exposed to air and served as controls. In group 3, 60 of the 120 males and in group 4, 60 of the 120 females were exposed to HMPA at a concentration of 50 ppm for 1 year and were placed in holding rooms. The remaining 60 males and 60 females were exposed continuously for 2 years. Group 5 males and group 6 females were exposed to HMPA at a concentration of 400 ppb for 10 months. Group 7

ABBREVIATIONS USED: HMPA = hexamethylphosphoramide; H & E = hematoxylin and eosin; PAS = periodic acid-Schiff.

[3] We thank our colleagues in the Pathology Division for technical assistance, Mr. J. W. Sarver for conducting the inhalation exposure, Dr. C. F. Reinhardt for criticism in the preparation of the manuscript, and Miss V. L. McCall for typing the manuscript.

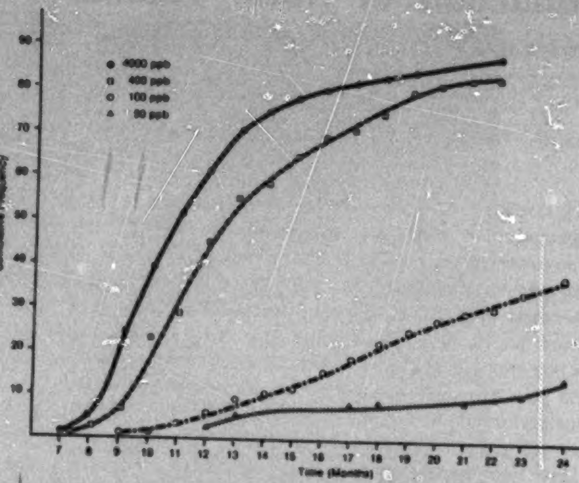
males and group 8 females were exposed at a concentration of 4,000 ppb for 9 months. After 3 months exposure necropsy was performed on 18 rats from each group. In the first 4 groups 6 and 20 rats were killed after 8- and 12-months exposure, respectively. The remaining rats in all groups were killed after a 2-year exposure.

In experiment II 800 young adult Charles River-CD Sprague-Dawley-derived rats were divided into 8 equal groups of 100 males and 100 females. Group 1-A males and group 2-A females were exposed to air and used as controls. Group 3-A male and group 4-A female rats were exposed to HMPA at 50 ppb for 2 years. Group 9 male and group 10 female rats were exposed to HMPA at a concentration of 10 ppb for 2 years. In group 11, 50 of the 100 males and in group 12, 50 of the 100 females were exposed to HMPA at a concentration of 100 ppb for 6 months. The remaining 50 males and 50 females were exposed continuously for 13 months. In groups 3-A male and 4-A female, 20 rats each were killed after a 1-year exposure. All rats were killed at the end of 2-years exposure, and subjected to microscopic examination except group 3-A male and group 4-A female rats. The lungs and tracheas, the thyroid-, pituitary-, and adrenal glands, the testes, and the kidneys were fixed in Bouin's solution; all remaining organs and tissues were fixed in 10% Formalin solution. The noses were fixed in Bouin's solution, decalcified, and three coronal sections from each anterior nasal cavity and two coronal sections from the posterior nasal cavity were prepared for light microscopy. The sections were stained either by H & E, or PAS method, Alcian blue, or by modified trichrome stain.

RESULTS

Tumor Induction

The incidence of nasal tumors is summarized in table [illegible] and shown in text-figure 1. Dose-dependence was observed with tumor incidence and latent period but not with tumor types or malignancy. Higher exposure concentrations produced more tumors with a shorter latent period. Nasal tumors were first detected after 7 months of exposure at 400 ppb and 4,000 ppb, after 9 months at 100 ppb, and after 12 months at 50 ppb. There were no remarkable differences in the tumor incidence, latency, or malignancy between male and female rats. Nasal tumor incidence was 83.3% at 4,000 ppb after 9-months exposure, 82.1% at 400 ppb after 10-months exposure, 19% at 100 ppb after 6-months exposure, 56% at 100 ppb after 13-months exposure, 15.7% at 50 ppb after 12-months exposure, and 25.7% at 50 ppb after 24-months exposure (table 2). A striking finding was that no marked differences in tumor incidence and latency occurred between the 400 and 4,000 ppb exposure levels despite the factor 10 difference in concentration. Fifty percent of the nasal tumors occurred within 10 months at 4,000 ppb exposure, within 12 months at 400 ppb, within 17 months at 100 ppb, and within 21 months at 50 ppb. Cessation of exposure after 1 year at 50 ppb and 6 months at 100 ppb did not completely disrupt tumorigenesis but markedly reduced tumor induction and increased tumor latency (table 2).



TEXT-FIGURE 1.—HMPA exposure concentrations are correlated with tumor induction. Higher exposure concentrations produced more tumors with shorter latent period. The curves for cumulative frequency of tumor induction at 400 and 4,000 ppb rise steeply up to 13 mo and gradually taper off, while the curves for 100 and 50 ppb rise gradually throughout the 24 mo.

Gross Pathology

In the early stages of tumor development, tiny tumor nodules were often seen at the nasoturbinals and nasal septum in the anterior nasal cavity (fig. 3), but not in the maxillary turbinates or in the ethmoturbinates. The tumor extended toward the posterior nasal cavity and invaded the ethmoturbinates (fig. 4) and occasionally the olfactory bulb of the brain (fig. 5). At the same time, the tumor expanded toward the dorsal nasal bone and bulged out after extensive destruction of the nasal bone (fig. 1). The nasal cavity was almost obstructed by the tumor and its internal structure was obliterated (figs. 2, 4). The gross findings of keratinized epidermoid carcinoma were characterized by tiny papillary projections and accumulation of pale yellow, friable, cheesy material, which was identified as the keratin material under microscopic examination (fig. 4). The cut surface of adenoid squamous carcinomas (fig. 2) and undifferentiated epidermoid carcinomas appeared smooth, moist, pale, and fleshy.

Histopathology

The nasal respiratory epithelium revealed acute inflammation, goblet cell hyperplasia, epithelial degeneration and desquamation, squamous metaplasia, and dysplasia (fig. 8). The dysplastic epithelium revealed loss of polarity, nuclear hyperchromatism, and mitotic activity. The acinar cells of subepithelial gland showed

hyperplasia and keratinized squamous metaplasia, which conglomerated with the squamous metaplasia developed from the epithelium. Pathologic lesions were often confined to the respiratory epithelia in the anterior nasal cavity and occasionally occurred in the ethmoturbinates of the posterior nasal cavity. The most striking finding was a massive accumulation of keratin material on the metaplastic respiratory epithelium in the anterior nasal cavity. The olfactory epithelium of the ethmoturbinates often showed squamous metaplasia with acute inflammatory reaction when malignant tumors were present in the anterior nasal cavity.

Typing of Nasal Tumors

Multiple sections of a nasal tumor often revealed mixtures of tumor cells originating from the glandular and epithelial cells. Also, there were mixtures of benign, malignant, and other types of tumors. Tumor typing was determined by the predominant malignant tumor cells when there were more than two different types of tumor cells in the sections. When tumors showed both benign and malignant tumor cells, the tumors were classified by malignant cells. Squamous cell papillomas were mostly exophytic. Inverted endophytic papilloma was relatively rare. Most squamous cell papillomas revealed marked hyperkeratosis, and there was no evidence of tumor invasion beyond the basement membrane (fig. 9). Adenomatous polyps were occasionally found with adenoid squamous carcinomas. The tumor growth was manifested by either invagination or projection with columnar or glandular epithelial lining (fig. 10). The basal membrane was intact with no evidence of tumor invasion into the submucosal layer. Adenocarcinomas (fig. 12) revealed tubular and acinar appearance with anaplasia and invasion. Epidermoid carcinomas were composed of squamous cells showing various degrees of differentiation and pleomorphism. Adenoid squamous carcinomas revealed glandular and and epidermoid structures (figs. 13, 14). The ratio of squamous to glandular cells varied, but in most cases squamous cells were predominant. Tumor cells formed duct-like structures containing PAS-Alcian blue-positive mucoid material. Most tumors were interspersed with cystic spaces forming a cribriform or lace-like pattern and were compatible with the adenoid cystic carcinoma in humans. Transitional papilloma (respiratory epithelial papilloma) consisted of the respiratory epithelial cells, and the basement membrane was intact and continuous with that of the remainder of the normal respiratory epithelium (fig. 11). Transitional carcinoma (respiratory epithelial carcinoma) was invasive and formed ribbon-like bands, and in many areas the tumor revealed intact basement

TABLE 2.—*Summary of nasal tumor incidence in rats exposed to HMPA for different exposure periods*

Group	Exposure concentration, ppb	No. of exposure months	Total No. of rats	Post-exposure month																			Total No. of tumors/ No. of animals examined (%)

membrane (fig. 16). Pleomorphic (mixed) tumors consisted of glandular, epidermoid, chondroid (fig. 17), or osteoid strucutres (fig. 18). One mixed tumor showing chondroid tissue metastasized to the lung and the cervical lymph nodes (fig. 21). It was difficult to determine the origin of undifferentiated tumors (fig. 19).

Incidence of Tumor Types and Anatomic Sites

Tables 1 and 3 show the incidence of nasal tumor, tumor types, anatomic location of the tumors, tumor invasion, and metastasis. Of a total of 473 nasal tumors, the predominant tumor type was epidermoid carcinoma (71.9%), followed by adenoid squamous carcinoma (15%), squamous cell papilloma (8.2%), transitional carcinoma (1.9%), adenocarcinoma (1.3%), undifferentiated tumor (1.1%), mixed tumor (0.4%), and adenomatous polyp (0.2%). Transitional papillomas occurred with transitional carcinomas. The frequency distribution of the tumor types was similar in all exposed groups and was not related to the exposure concentrations. The incidence of nasal tumors in the anterior nasal cavity was 59%. Only 0.4% of the primary tumors was found in the ethmoturbinals of the posterior nasal cavity. The anterior and posterior nasal cavities contained 41% of the tumors. Most benign tumors were confined to the anterior nasal cavity. The nasal bone was invaded by 48% of all nasal tumors; epidermoid carcinoma incidence in this group was 52.9%, adenoid squamous carcinoma, 52.1%, adenocarcinoma, 33.3%, transitional carcinoma, 11.1%, undifferentiated tumor, 80%, and mixed tumor, 100%. Tumor invasion of the brain (figs. 5, 20) occurred in 1.1% of the total nasal tumors, in 4 of 340 epidermoid carcinomas (1.2%), and in 1 of 71 adenoid squamous carcinomas (1.4%). Tumor metastasis to the lung (figs. 7, 23) was seen in 1.5% of all nasal tumors, in 4 of 340 epidermoid carcinomas (1.2%), and 3 of 71 adenoid squamous carcinomas (4.2%). Of all nasal tumors, 1.1% metastasized to the cervical lymph nodes (figs. 6, 21, 22); 5 of 340 epidermoid carcinomas (1.5%) metastasized to the cervical lymph nodes.

Malignancy of Epidermoid Carcinoma

The epidermoid carcinomas were divided into four grades on the basis of cellular differentiation and degree of keratinization. In grade 1, more than 75% of the tumor cells were differentiated, in grade 2, more than 50% were differentiated, in grade 3, more than 25%, and in grade 4, less than 25%. Grade 1 epidermoid carcinoma consisted mainly of mature squamous cells with intercellular bridges and numerous horn pearls (figs. 15, 24). The tumor still showed some areas of intact basal layer and disorganized basal layer with tumor cell invasion of the submucosa. In grade 2 epidermoid carcinoma, a fairly large number of squamous cells were atypical and keratinization was much less evident than in grade 1. The invading tumor cells were poorly demarcated from the surrounding tissue (fig. 25). Grade 3 epidermoid carcinoma revealed minimal keratinization and the large typical horn pearls almost disappeared. The majority of tumor cells were atypical with a few intercellular bridges and conspicuous mitotic figures (fig. 26). In grade 4, nearly all tumor cells consisted of atypical spindle shaped cells and lacked intercellular bridges and keratinization. The tumors resembled fibrosarcoma, although some areas still showed tiny foci of squamous cells (fig. 27).

Tables 4 and 5 show the incidence of graded epidermoid carcinoma, anatomic location, and tumor invasion to the nasal bone. There were no significant differences in the incidence of graded epidermoid carcinoma among the exposed groups and tumor differentiations were not related to exposure concentrations. Most of the epidermoid carcinomas were well-differentiated and the incidence was 79.4% in grade 1, 11.2% in grade 2, 5.2% in grade 3, and 4.1% in grade 4. The tumor invasion of the nasal bone was clearly related to tumor grades: 46.7% of grade 1, 68.4% of

TABLE 3.—*Anatomic sites of nasal tumor, incidence of nasal bone destruction, and metastasis in rats exposed to HMPA*

Tumor types	Incidence/No. of rats (%)

grade 2, 77.7% of grade 3, and 100% of grade 4 tumors invaded the nasal bone. Also, tumor grades were related to the extensiveness of tumor involvement in the nasal cavity. Tumor invasion in both the anterior and posterior nasal cavity was 37.0% in grade 1, 52.6% in grade 2, 77.7% in grade 3, and 71.4% in grade 4.

DISCUSSION

Nasopharyngeal cancer in humans is a rare cancer in most countries of the world; however, it is a significant cancer problem in East and Southeast Asia. The incidence of nasopharyngeal cancer among Chinese and some Southeast Asian peoples is 10–50 times higher than in the rest of the world. Nasal tumors resulting from occupational exposure have been reported in workers at nickel refineries (*18–20*) and in the furniture (*21, 22*) and shoe industries (*23, 24*). The nasal tumors observed in the furniture industry were mostly adenocarcinomas, while a variety of tumor types were found in shoe factory workers. Tumors in the nickel refinery workers developed predominently in the ethmoid region of the nasal cavity (*22*).

The tumor type, anatomical location, invasiveness, and metastases in the nasal tumors induced by HMPA were similar to those seen in human nasal tumors (*29–40*). These microscopically detected small tumors were exclusively in the anterior region of the nasal cavity, especially in the nasoturbinals and nasal septum. The nasal tumors arose mostly from respiratory epithelium of the anterior nasal cavity and subsequently extended toward the posterior region involving the ethmoturbinals. HMPA-exposure concentrations correlated with carcinogenicity and latency of tumors at the levels of 50, 100, and 400 ppb but there was no remarkable correlation between 400 and 4,000 ppb. We observed that the carcinogenicity and latency are dose-related up to a certain upper threshold for HMPA carcinogenicity, but beyond that limit the dose-response relationship decreases. The decrease in dose-related carcinogenicity is possibly caused by an almost complete saturation of cell receptor sites by HMPA molecules and the subsequent decline in HMPA-reactivity at the receptors. Dose-related carcinogenicity was described for various chemical carcinogens including polycyclic aromatic hydrocarbons, aromatic amine derivatives, alkylating drugs, and alkylnitrosamines (*37*). However, the total cumulative dose necessary for carcinogenesis with small daily doses was smaller than the single dose required to produce an equivalent response (*38, 39*).

A large number of nitrosamine compounds have been known to cause cancers of the nasal cavity in laboratory animals. Diethylnitrosamine produced squamous cell carcinomas, adenocarcinomas, and olfactory neuroepitheliomas in hamsters (*40*). Subsequently, many investigators have reported that squamous cell carcinomas, adenocarcinomas, and esthesioneuroepitheliomas were induced by a wide variety of nitrosamines (*41*). Carcinomas originating from the olfactor epithelium in the posterior nasal cavity were induced in hamsters by nitroso-compounds (*42*). The adenocarcinomas and undifferentiated carcinomas were mostly induced in the posterior region of the nasal cavity in hamsters by subcutaneous injection with methyl-*n*-propylnitrosamine (*43*) or by intratracheal instillation with dimethylnitrosamine (*40*). The anatomic sites and tumor types produced by nitroso-compounds differ from those of HMPA-induced nasal tumors. A striking trait of nitroso-compounds is their strong organotropism for certain target organs which resulted in tumors in more than one organ by subcutaneous injection or oral administration. In contrast, there was no carcinogenic effect in the rats fed HMPA for 2 years (*44*). The animal experiments suggest that nitrosoamines not only have a local carcinogenic effect but are also transported in the bloodstream to the nasal cavity where they are excreted or metabolized into carcinogens. The administration of large doses of nitroso-compounds produced high multiplicity of neoplasms with short survival times and tumor latency (*45–48*). The low dose of di-*n*-propylnitrosoamine produced mostly benign epidermoid-, or mucoepidermoid tumors and polyps, whereas the highest dose also induced carcinomas in the posterior region of nasoturbinals and ethmoturbinals (*49*). In contrast, there were no remarkable differences in tumor types between the low and high dose groups of rats exposed to HMPA.

The following industrial chemicals have been known to cause nasal tumors in experimental animals: phenyl glycidyl ether (*50*), 1,4-dichlorobutene-2 (*51*), 1,2-dibromo-3-chloropropane (*52*), dimethylcarbamoyl chloride (*53*), epichlorohydrin (*54*), chloromethyl methylether (*55*), bis(chloromethyl)ether (*56*), hydrogen chloride and formaldehyde (*57, 58*), 1,4-dioxane (*59, 60*), dimethyl sulfate (*61*), quinoxaline 1,4-dioxide (*62*), and 1,2-dibromoethane (*63*). An important question to consider is how to extrapolate the HMPA-produced nasal tumors of rats to humans. In spite of many years of occupational or environmental exposure of man to some of these chemicals, we found no epidemiological studies indicating potential carcinogenic hazard to man by those industrial chemicals that are specific in causing only nasal tumors in animals. Human risk in HMPA-exposure can be better assessed by conducting extensive epidemiological studies in man. Workers exposed to chloromethyl methyl ether were shown to have an eight times higher than expected incidence of lung cancers and tumors, mainly of the oat cell type (*64*). Other studies have implicated lung cancers as the cause of death in workers exposed to bis(chloromethyl)-ether (*65, 66*). However, these two industrial chemicals have produced not only nasal tumors but also lung cancers in experimental animals.

Remarkable organotropism and carcinogenic effect on the nasal cavity were found in rats administered 1,4-dioxane in drinking water (*39, 40*) or by sc injection of dimethyl sulfate (*61*). Squamous cell carcinomas were induced mainly in the anterior nasal cavity of the animals exposed to phenyl glycidyl ether, 1,4-dichlorobutene-2, formaldehyde, 1,4-dioxane, and epichlorohydrin, whereas 1,2-dibromoethane produced predominantly adenomatous polyps and adenocarcinomas. In contrast, chloromethyl methyl ether and bis(chloromethyl) ether induced neurogenic carcinoma, mainly esthesioneuroepitheliomas in the posterior nasal cavity.

The toxic effects of HMPA-inhalation were sharply limited to the upper respiratory air passages, decreasing markedly in lower air passages without any effects on alveolar walls. Generally, the sites of toxic effects from most gases and fumes are dependent upon their water solubility and irritability. Highly water soluble substances (ammonia and hydrogen chloride) are absorbed into the mucous membrane contacted first, specifically in the nose and upper respiratory passages. In contrast, slightly water soluble substances (oxides of nitrogen, chlorine and phosgene) exert their toxic effects throughout the lower respiratory tracts and alveolar walls. Since HMPA is water soluble, its inhaled vapor appears to be absorbed mostly at the respiratory epithelium of the anterior nasal cavity, failing to provoke tissue response in the lower respiratory passages and alveoli.

In comparison with the nasal cavity of humans, the entrance and the exit of the nasal cavity of the rat are narrower, the nasal cavity is markedly longer, and the Jacobson's organ is larger. Another peculiarity of the rat is broad communication between the right and left nasal airway through the nasal septum at the posterior nasal cavity. The ethmoturbinates of the rat form complicated interdigitated structures that easily block drainage of inflammatory exudate and air passage. After exposure to HMPA, the interspaces between the ethmoturbinates were packed with inflammatory exudate when the anterior nasal cavity was occupied by the tumor mass. There are marked differences in patterns of respiration between the rat and man. The rat is an obligatory nose breather, and has a greater surface area-to-volume ratio of the upper respiratory tract than man (*67*). Because of these physioanatomical differences, the nasal cavity of the rat may be more susceptible to irritants and may develop more severe pathological changes than man when exposed to equal concentrations per body weight of irritants for equal amounts of time.

Compared to man, the rat has an approximately eight times higher pulmonary ventilation rate in terms of liters of air per minute per kilogram body weight. Therefore, rats can receive a higher net effective dose of HMPA for any given concentration and duration of exposure. Air flow patterns during respiration in rats permit incoming and outgoing air to directly contact the anterior-ventral region of the nasal cavity (*18*). Due to this unique air flow pattern, HMPA vapors are in constant contact with the anterior-ventral region of the nasal cavity during exposure. Inflammation and squamous metaplasia or dysplasia were often observed with nasal tumors in the respiratory epithelium of the rat's anterior-ventral nasal cavity. The fact that the epithelial surface of the nasoturbinals is larger than that of the maxilloturbinals should explain the higher incidence of nasal tumors in the nasoturbinates. The destruction of ventral nasal bones by tumor invasion is related to the preponderance of the nasal tumors in the nasoturbinates.

Figure 1.—Dorsal surface of the nose is rounded due to bulging nasal tumor on the nasal bone.

Figure 2.—Cut surface of the nasal tumor shown in fig. 1. Architecture of nasal cavity is extensively obliterated by the tumor and the ethmoturbinates (E) are replaced with tumor extending from the anterior nasal cavity. (T) tongue, (C) cranial cavity, (h) hard palate.

Figure 3.—Sagittal section of the nasal cavity shows papillary tumor growth (P) in the nasoturbinate and nasal septum (S) at the anterior nasal cavity. (T) incisor tooth.

Figure 4.—Serial cross-section of the nasal cavity illustrates the tumor (*asterisks*) in the right nasal cavity throughout anterior and posterior region. Nasoturbinate and ethmoturbinate are almost completely obliterated by the tumor.

Figure 5.—Olfactory bulb and anterior region of brain are replaced with the invading nasal tumor (T) from the ethmoturbinate in the posterior nasal cavity.

Figure 6.—Markedly enlarged cervical lymph node (L), due to metastatic tumor from the nasal cavity. (S) salivary gland.

Figure 7.—Numerous metastatic tumor nodules (*arrows*) in lung, varying in size in the pleural surface.

Figure 8.—Squamous metaplasia (S), dysplasia (D), and normal respiratory epithelium (E) in the nasoturbinate. *Note* diffuse dense infiltration of acute inflammatory cells in the nasoturbinate and acute inflammatory exudate in the nasal cavity. H & E. × 100

Figure 9.—Squamous cell papilloma. *Note* long papillary projections (P) of epidermoid cells with massive keratin (K) accumulation. The basement membrane (*arrows*) is intact with no evidence of tumor invasion into the submucosa. H & E. × 100

Figure 10.—Adenomatous polyp. Polypoid protrusion consists of glandular structure showing cystic acini filled with eosinophilic secretion (S). H & E. × 100

Figure 11.—Transitional papilloma (respiratory epithelial papilloma) consists of columnar respiratory epithelium (E). *Note* a folded junction (*arrow*) between normal ciliated respiratory epithelium (R) and papillary projection. H & E. × 250

Figure 12.—Nasal bone (B) is invaded by adenocarcinoma showing acinar structure with eosinophilic secretion (S). H & E. × 250

Figure 13.—Adenoid squamous carcinoma shows a mixture of epidermoid (*large arrows*) and glandular structures showing acini with secreting material (*small arrows*). H & E. × 250

Figure 14.—Adenoid squamous carcinoma with PAS-positive secretion in the glandular acini (*arrows*) under intact respiratory epithelium (E). Adjacent epithelium shows epidermoid carcinoma (C). PAS. × 250

Figure 15.—Cross section of the anterior nasal cavity shows large epidermoid carcinoma bulged out on the destroyed nasal bone. *Note* the tumor involvement in the nasoturbinate (N). (B) nasal bone, (S) nasal septum, (M) maxilloturbinate, (P) pulp of incisor tooth, (J) Jacobson's organ, and (L) nasolacrimal duct. H & E. × 6.2

Figure 16.—Transitional carcinoma (respiratory epithelial carcinoma) consists of anaplastic respiratory epithelial cells with numerous mitotic figures (*arrows*). H & E. × 250

Figure 17.—Pleomorphic tumor (mixed tumor) shows the anaplastic chondroid (C) and epidermoid (E) cells. The chondrocytes reveal irregular sizes and shapes and disorderly cellular arrangement. H & E. × 250

Figure 18.—Pleomorphic tumor (mixed tumor) reveals numerous giant cells (*arrows*), osteoid (O) and undifferentiated spindle-shaped squamous cells (S). H & E. × 100

Figure 19.—Undifferentiated tumor shows large, anaplastic, bizarre giant cells H & E. × 250

Figure 20.—Epidermoid carcinoma (E) invading the olfactory bulb (O). *Note* absence of keratinization in the tumor cells showing intercellular spaces, hyperchromatic nuclei, and distinct nucleoli. H & E. × 250

Figure 21.—Metastatic pleomorphic tumor (mixed tumor) in the cervical lymph node. *Note* chondroid (C) tissue showing irregularly arranged chondrocytes in the lymphoid tissue (L). H & E. × 250

Figure 22.—Metastatic epidermoid carcinoma in the cervical lymph node. Cystic spaces (S) are filled with laminated keratin, denuded cells, and cellular debris. Wall of cysts is lined with well-differentiated epidermoid cells. (L) lymphoid tissue. H & E. × 100

Figure 23.—Metastatic epidermoid carcinoma in the lung. Tumor (T) compresses adjacent alveolar walls and forms slit-like air spaces. (A) alveolar air space. H & E. × 100

Figure 24.—Epidermoid carcinoma, grade 1. Tumor cells consist of mature squamous cells showing intercellular spaces with bridges, marked keratinization, keratin pearls (P), and disrupted basement membrane. H & E. × 450

Figure 25.—Epidermoid carcinoma, grade 2. Large number of squamous cells are atypical and disorganized (*arrows*) with acute inflammatory cell infiltration. Squamous cells show clear intercellular spaces with bridges (*slender arrow*) and scanty keratinization (K). H & E. × 450

Figure 26.—Epidermoid carcinoma, grade 3. The tumor consists of admixture of epidermoid cells (E) and spindle-shaped cells (S) with mitotic figures (*small arrows*). *Note* transition (*large arrows*) from epidermoid to spindle cells. H & E. × 450

Figure 27.—Epidermoid carcinoma, grade 4. Majority of tumor cells are spindle-shaped cells with hyperchromatic nuclei and numerous mitotic figures (*arrows*) resembling fibrosarcoma. H & E. × 450

Meeting Highlights

Host Factors in Human Carcinogenesis[1]

"You can leave benzo[*a*]pyrene in a test tube forever, and it will never cause cancer," was the gist of a remark from the floor during the Symposium. Also, since only one out of every seven smokers gets lung cancer, more than cigarette smoking must be involved. These observations help explain why the International Agency for Research on Cancer, which has long focused on environmental factors as the cause of most human cancers, convened some 100 scientists to discuss host factors. The effect of even the most powerful carcinogen is likely modified and modulated by host factors. Invited participants (two laboratory scientists for each clinician or epidemiologist) stumbled repeatedly over the scope of the term "host factors." Some drew a line at DNA (i.e., purely genetic), and others at the mouth, nose, skin, and other body portals to the environment. Should internal estrogens be considered as host factors but not medicinal steroids? Where should nutrition be placed? To resolve the dilemma, several discussants preferred the classic dichotomy of Sir Francis Galton, the father of human genetics: genes and environment.

Introductory overviews gave evidence of host factors as seen by epidemiology (e.g., relating breast cancer to body form, reproductive status, and hormone levels), by laboratory experimentation (showing multiple interactions among such factors as DNA, exogenous chemicals, and membrane receptors), and by clinical medicine (observing peculiar occurrences of cancer that demonstrate gene-environment interaction).

The session on genetics indicated that each technical advance in visualizing human chromosomes strengthens the 1914 hypothesis of Boveri that cancer is related to chromosomal imbalance. For example, the prophase staining method (which now distinguishes 1,000 bands, in contrast to the 250 bands distinguished by standard techniques) revealed a small deletion in the short arm of chromosome 11 in patients with the Miller syndrome of aniridia-Wilms' tumor. Still, best techniques lack the power to locate individual cancer genes. When methods emerge, karyotyping solid tumors should be as useful as are the present prognostic and etiologic insights gained for the lymphoproliferative cancers. For example, many potential determinants of Burkitt's lymphoma besides the Epstein-Barr virus and malaria became suspect when it was shown that chromosome 14 has the gene for nucleoside phosphorylase near the break point at which translocation often occurs in Burkitt's lymphoma. In this connection, deletion of DNA sequences was noted to be a normal phenomenon in the synthesis of specific immunoglobulins with sometimes sloppy deletion and insertion of genetic material. The story begins to resemble the emerging principles of the action of retrovirus in murine and avian carcinogenesis.

The intense efforts in the pursuit of the elusive human cancer virus led to nucleic acid chemical techniques that dissect the genetic material better than the best chromosome banding methods. The present view is that long ago viral DNA sequences became integrated into human genes and may now mediate the initiation of cancer when they are transcribed at an inappropriate time in the cell cycle. Such transcription may be stimulated by genes transposed as a result of a chemical or physical agent. R. Weiss claimed, "Viruses may be considered endogenous host factors," supporting I. B. Weinstein's earlier remark, "Today's environmental factors are tomorrow's host factors."

Similar progress has occurred in explaining the relations between mutagens, carcinogens, and the mechanisms for repairing DNA as measured by in vitro studies of radiosensitivity of cells from patients at risk for cancer or with unusual reactions to radiation. The story is best shown by two autosomal recessive genetic conditions, xeroderma pigmentosum and ataxia-telangiectasia, and continues to develop as other disorders are studied. The insights, of course, are not limited to radiation carcinogenesis but include chemicals that mimic the action of photons.

The hunt for an RNA human cancer virus took a fruitful but unexpected turn. In contrast, evidence of a significant etiologic role of hepatitis B virus in the origins of hepatocellular carcinoma continues to mount in the model of a classic infectious disease. Since only 5% of hepatitis B virus carriers get liver cancer, additional factors must operate (such as exposure to aflatoxins and other hepatotoxins, early age of infection, or genetic predisposition). No one factor seems sufficient; several must act together.

If defects of DNA or gene action can be considered as initiators of cancer, surely host factors remain that could be considered promoters in modifying the clinical expression of cancer. Possibilities include genetically modulated variations in nutrition, hormones, and immunologic function. For example, exogenous estrogens seem to set up tissues for initiation and may help the action of other carcinogens, but they never seem to be initiators.

Another session was devoted to inborn variation and genetic differences in response to environmental agents (carcinogens), a field that could be termed "ecogenetics." The best examples in humans concern variations in drug metabolism—pharmacogenetics—exemplified by the recent finding of a probable excess of rapid metabolizers of debrisoquine among cancer patients in Ibadan. Further studies of drug metabolism in monozygous twins show differences resulting from surprisingly subtle environmental factors that are poorly recognized, such as interaction with other drugs, time since last meal, and antecedent or concurrent disease. The major point remains that the same genetically determined enzyme systems that metabolize drugs handle chemical carcinogens. Despite detailed knowledge of the homologous *Ah* locus in the mouse, the great expectation that aryl hydrocarbon hydroxylase inducibility would predispose some people to tobacco-associated cancer has not been substantiated. Contrary to the hope of epidemiologists, laboratory scientists at the meeting left little doubt that the complexities of monooxygenases are now poorly understood.

---

[1] The International Agency for Research on Cancer organized the Symposium, held in Cape Sounion, Greece, June 8-11, 1981.

[2] ARMSTRONG BK, BARTSCH H, eds. Host factors in human carcinogenesis. IARC Sci Publ No. 39. Lyon: IARC, 1981.

Just before a summarizing session, a potpourri of new approaches to the study of host factors in cancer was given. Immunologic and mass spectrophotometric assays, in part with the use of monoclonal antibodies, blend the high technology of several disciplines to achieve a sensitivity of detecting one molecule of DNA-carcinogen adduct per cell; such precision makes biologic interpretation a problematic task. Assays with the use of organ explants, cell transformation, and mutagenicity are continually being refined. Finally, exploring the biology of preneoplastic states should provide insights into anatomic and physiologic correlates of carcinogenesis and, perhaps, be of immediate use in prevention; e.g., abnormal sugar metabolites are found in intestinal metaplasia of the gastric epithelium in patients at high risk for stomach cancer.

Despite an idyllic setting, it was not clear that many lasting romances had been made between laboratory approaches studying DNA and clinical-epidemiologic strategies with populations. This perspective may change during the gestational period for the anticipated publication of the proceedings by the International Agency for Research on Cancer.[2]

Announcements

The Journal will publish notices of major meetings dealing with cancer. Submission of notices 6 months in advance is requested to permit timely publication.

Sixteenth Annual Clinical Symposium

St. Jude Children's Research Hospital will hold its Sixteenth Annual Clinical Symposium in Memphis, Tennessee, on February 26-27, 1982. The symposium will be concerned with current results in the treatment of children with cancer and leukemia. Emphasis will be given to diagnosis and treatment programs for primary disease, and the care of complications. There will be discussions of various aspects of supportive care as an essential adjunct to chemotherapy regimens.

There are no registration or other fees for this symposium. Physicians may register by writing to: Associate Director for Clinical Research, St. Jude Children's Research Hospital, Box 318, Memphis, Tennessee 38101.

Thirty-Second Annual Conference of The National Council on the Aging, Inc.

"The 'American Dream'—Assessing the Status of Older Americans" will be the topic of this conference to be held at the Sheraton Washington in Washington, D.C., on March 31-April 3, 1982. Conference participants will focus their attention on the following areas: achieving economic security, assuring quality of life, and creating responsive services.

For further information contact the Conference Department, The National Council on the Aging, Inc., West Wing 100, 600 Maryland Avenue, S.W., Washington, D.C. 20024 (telephone: 202-479-1200).

Oncology Update 1982

The Northridge Hospital Medical Center will sponsor this symposium to be held at the Biltmore Hotel, Los Angeles, California, on April 3, 1982. The symposium will focus on the latest developments in cancer treatment and research including alternatives in primary management of breast carcinoma, emotional and psychological factors that have impact on the lives of cancer patients, results now achieved with newer chemotherapeutic agents, and the role of highly specific antibodies in the management of the cancer patient.

For reservations or further information please contact Ms. Sandra Rossen, Northridge Hospital Medical Center, Medical Education Department, 18300 Roscoe Boulevard, Northridge, California 91328 (telephone: 213-885-5311).

North American Society for Cardiac Radiology—1982 Postgraduate Course

"Cardiac Interventional Techniques and Diagnostic Imaging" is the subject of this course to be held at the Barbizon Plaza Hotel, New York, New York, on April 5-6, 1982. The subject fields to be covered are digital subtraction angiography, nuclear magnetic resonance, echocardiography, radionuclide studies, and interventional measures and techniques, e.g., shunts, ergonovine, PTCA, and PTA. Attention will be directed to pathophysiologic conditions such as congenital and acquired heart disease, fibrinolysis, venous hypertension, valvular heart disease, and diagnostic imaging.

For additional information contact Dr. Thomas A. Sos, Program Chairman, c/o Educational Resources Associates, Inc., 209 Harvard Street, Suite 500, Brookline, Massachusetts 02146 (telephone: 617-738-8859/8861).

Second Annual Washington Imaging Conference

The Department of Radiology of The Alexandria Hospital and the American College of Radiology will sponsor this conference to be held at the Washington Marriott Hotel, Washington, D.C., on May 2-7, 1982. "Recent Advances in Computed Tomography and Digital Imaging" will be the subject of the conference, and topics will include computed tomography of the abdomen, chest, pelvis, and spine, and digital angiography.

For further information please contact: Miss Susan Ferraro, Department of Radiology, The Alexandria Hospital, 4320 Seminary Road, Alexandria, Virginia 22304 (telephone: 703-379-3102).

Fourth Annual Course in Flow Cytometry

"Applications in Cell Biology" is the title of this course to be presented by the University of Rochester School of Medicine and the Department of Pathology and Cancer Center, at the University of Rochester, Rochester, New York on May 24-28, 1982. Lectures will include instrumentation description, cytochemistry, immunological analysis, and cell cycle analysis.

For additional information please contact Dr. Paul K. Horan, Course Director, Department of Pathology, Box 626, University of Rochester Medical Center, 601 Elmwood Avenue, Rochester, New York 14642 (telephone: 716-275-5516).

Educational Video Cassettes

To help health professionals recognize and manage patients at increased risk of melanoma, NCI investigator Dr. Mark H. Greene and his colleagues have developed a series of educational video cassettes. These materials illustrate the unique clinical and histologic characteristics of dysplastic nevi, the recognition of early melanoma, the melanoma warning signals, principles of skin examination, ways to minimize sunlight exposure, and recommendations for daily health care.

For additional information on obtaining educational video cassettes and written information on the prevention and early detection of malignant melanoma in persons at high risk, please contact: The National Cancer Institute, Office of Cancer Communications, Building 31, Room 10A18, Bethesda, Maryland 20205 (telephone: 301-496-6641).

HE 20. 3161:

This month's cover (*top*) shows the overall survival curves based on age at death of three sex categories of pigs with untreated lymphosarcoma: females, entire males, and castrated males. The photograph (*bottom*) is of a 10-month-old male pig affected by hereditary porcine lymphosarcoma. The pendulous abdomen and arched spine were caused by gross enlargement of visceral lymph nodes and of the spleen (*see* article by McTaggart, Imlah, and Head on pages 239–248).

JNCI Journal of the National Cancer Institute

February 1982
Volume 68
Number 2

THE JOURNAL of the National Cancer Institute solicits manuscripts on original observations in laboratory and clinical research from all scientists. A manuscript is considered for publication with the understanding that it has not been published previously and is submitted exclusively to the Journal. Opinions expressed by the authors are not necessarily those of the publisher or its editors.

THE JOURNAL is published monthly (two volumes a year). The Secretary of Health and Human Services has determined that the publication of this periodical is necessary in the transaction of the public business required by law of this Department.

A MONOGRAPH SERIES covering proceedings of scientific meetings pertaining to cancer is also published. These books may be purchased from the Superintendent of Documents. Series subscriptions are not available and monographs are not included in a subscription to the Journal.

THE JOURNAL is for sale by the Superintendent of Documents, U.S. Government Printing Office, Washington, D.C. 20402. Price per copy, $6.00. Subscription price for two volumes per year in the United States, $65.00; foreign, $81.25. Payment is required in advance, and check or money order should be made payable to the Superintendent of Documents.

All inquiries regarding purchase of subscriptions or depository library distribution, including inquiries about missing issues and change of address, should be addressed to the Government Printing Office. The Government Printing Office requires payment in advance on all orders. Inquiries regarding missing issues or change of address for official subscriptions should be addressed to the Editorial Office, Room 850, Westwood Building, 5333 Westbard Avenue, Bethesda, Md. 20016.

Instructions to Authors

Text: Send one original and two copies. **Text-figures** (graphs, charts, and line drawings): Send one original and two copies. **Figures** (photomicrographs and photographs): Send three original glossy prints, unmounted. **Tables:** Send tabular material in typewritten form; do not submit tables as glossy prints to be photographed. The entire manuscript including footnotes, legends, and references must be typed double spaced. Single-spaced portions of a manuscript will be returned to the author for retyping. The mailing address is: Journal of the National Cancer Institute, Westwood Building, Room 850, 5333 Westbard Avenue, Bethesda, Maryland 20016.

Manuscripts should be accompanied by a covering letter from the author responsible for correspondence about the manuscript. The covering letter should contain a statement that the manuscript has been seen and approved by all authors and that all persons listed as authors have made significant (not merely administrative, technical, or supervisory) contributions to the content of the paper. The letter should also state that the manuscript or substantial portions thereof have not been previously published nor are they under consideration for publication in another journal.

Data too extensive for inclusion in a manuscript, but which may be of interest to other investigators, may be deposited with the National Auxiliary Publications Service (NAPS), c/o Microfiche Publications, P.O. Box 3513, Grand Central Station, New York, New York 10017. Authors using the NAPS facilities should indicate in a footnote how their additional data may be obtained.

TITLE: Be brief (no more than 14 words, if possible), but for indexing purposes include all key words. The annual subject index is prepared directly from the titles. Titles that form complete sentences are not acceptable. Do not use abbreviations or chemical formulas in titles.

BYLINE: Supply the complete first name, middle initial, and last name of each author. Avoid use of nicknames. Academic degree is optional; however, if a degree is provided for one author, it should be provided for all authors on a manuscript. Include the name of the institution, address, and zip code for each author. Indicate address for reprint requests in a footnote on the byline.

ACKNOWLEDGMENTS: Financial aid in support of research should be recognized in a footnote. Aid in technical fields, animal care, photography, stenography, and other areas may be mentioned in a separate footnote. Indicate the title (Dr., Mr., Mrs., Miss, Ms.) and affiliation of each person acknowledged.

ABSTRACT: Provide an abstract, 150 words or less, on a separate page. The abstract should describe only *results* of the work being reported. Speculation, historical background, or reference to published works will be deleted from abstracts. Any inbred strains, noninbred stocks, cell lines, or other living materials used in the work should be noted in the abstract.

TEXT: Avoid the use of laboratory jargon and abbreviations not in common usage. When possible, refrain from the use of abbreviations that form words (exceptions are PAGE, ALL). Whenever possible, write mathematical equations and chemical formulas on a single line; submit complicated chemical structures as artwork. Avoid repetition of data in the text when it is presented in tables or text-figures.

Use the following style sources: Webster's *Third New International Dictionary* and Dorland's *Illustrated Medical Dictionary* (25th ed) for spelling; *Council of Biology Editors Style Manual* (4th ed) for scientific abbreviations and symbols: *Government Printing Office Style Manual* for other abbreviations and symbols, punctuation, and hyphenation; *Biochemical Nomenclature and Related Documents* (IUB, 1978) for abbreviations of chemical substances; *Enzyme Nomenclature*, recommendations (1978) of the IUB for recommended names of enzymes and information on nomenclature of isozymes; *The Merck Index* (9th ed) for chemical compounds; "Standard Nomenclature for Inbred Strains of Mice: Seventh Listing" by Joan Staats (Cancer Res 1980;40:2083-2128) for inbred mouse strains; "Standardized Nomenclature for Inbred Strains of Rats: Fourth Listing" by Joan Staats and Michael Festing (Transplantation 1973;16:221-245) for designations of inbred rat strains; *Animals for Research* (9th ed) prepared by the Institute of Laboratory Animal Resources, National Academy of Sciences, for designations of laboratory animal stocks and strains.

TABLES: Submit tabular material typed double spaced on a separate page. Computer print-outs of tables are acceptable only if they are double spaced and with satisfactory title, column headings, legends and other textual material. Provide headings for all columns of a table and indicate units of measurement where applicable.

TEXT-FIGURES: Refer to graphs, charts, and line drawings as text-figures. Make the abbreviations on text-figures identical to the abbreviations used in the text and legends. Symbols and lettering should be large enough to be legible if reduced. Glossy prints or original drawings in black ink are acceptable; orient vertically instead of horizontally.

FIGURES: Refer to photomicrographs and photographs as figures. Figures and their legends should fit a 7.5- by 9-inch dimension. Calculate that nine typewritten lines of legend will require 1 inch of vertical space. Type figure legends on a separate sheet and identify in the legend any lettering used on the figure. Trim photographs to show only important areas. Do not number face of photographs; use the back or overlay to indicate the top and number of each. Printed indicators may be included on photographs; do not use hand-drawn indicators. *Insert internal scale markers on all photomicrographs.* Color photographs must be grouped as a single plate. For color reproduction, submit both color transparencies and high-quality black and white reproductions. The need for color must be documented before it will be considered.

REFERENCES: Use any recent issue of the Journal as a style guide for reference lists. Number references in order of citation in both text and reference list. For periodicals, provide author(s), title of paper, journal, year, volume, and first and last page numbers. For books, give the author(s), title, name(s) of editor(s), location and name of publisher, year, pertinent chapter or section title, and page numbers. Follow *Index Medicus* for punctuation and abbreviations. Citations of papers in preparation or submitted for publication, unpublished observations, and personal communications should be noted parenthetically in the text. Do *not* include them in the reference list. The accuracy of all references is the responsibility of the authors and not of the editorial staff.

LETTERS TO THE EDITOR should pertain to recent articles in the Journal and should not contain new data unless relevant to the discussion of a particular paper. The authors addressed will be invited to reply to comments before correspondence is published. Letters will be edited by the Staff, subject to contributor approval.

FURTHER DETAILS on the preparation of manuscripts are set forth in the document "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" prepared by the International Steering Committee of medical editors (*see* Am Rev Respir Dis 1979;119:3-10/Ann Intern Med 1979;90:95-99/Br Med J 1979;1:532-535/Lancet 1979;1:428-430).

Herbert Joseph Rapp

1923-1981

Dr. Herbert J. Rapp, Chief of the Laboratory of Immunobiology of the National Cancer Institute for the past 15 years, died on September 25, 1981. His untimely passing represents a great loss to science, to his family, and to his friends and colleagues.

Herb was born in Philadelphia on January 15, 1923; during the Great Depression his family moved to Ocean City, Maryland, where he finished his high school studies. He entered engineering school at The Johns Hopkins University in Baltimore; the Second World War interrupted this course of study, and for the duration of 1943–1946 he served in the U.S. Navy Hospital Corps, primarily at the Naval Hospital in Bethesda. After his discharge from the services, Herb turned away from engineering and studied biological sciences, with a strong stress on chemistry and his beloved subject, mathematics. The year 1948 was a crucial one for Herb: He married the former Marion Wasserman and got a job as a clinical laboratory technician at The Johns Hopkins Hospital; both of these events were to shape his life permanently. The marriage produced four children, Barbara, Margaret, Brian, and Frances, who were his pride and joy to the end of his days. The Hopkins job led him to Manfred M. Mayer, the newly arrived "Wizard of Complement" at the Department of Microbiology at the School of Hygiene and Public Health, who hired Herb as a technician and then kept him on as a graduate student until he obtained his M.Sc. in 1953 and his Sc.D. in 1955.

Herb's contributions to science are numerous and span a wide range of subjects. The title of his doctoral dissertation reveals his love for mathematics: "A Mathematical Theory and Analysis of Immune Hemolysis." His ability to apply mathematical analysis to complex problems never left him. His work at Hopkins was taken up by research on complement, and his two major contributions in that field left a permanent legacy: the quantitation of the activity of complement and its components on a sound theoretical basis and the separation of the components of complement by modern physicochemical methods. The result of these two approaches was the discovery that the then recognized third component comprised at least three distinct entities. Herb's work truly laid the foundation of the modern era of complement research.

In 1962 Herb was invited to head the Immunology Section of the Diagnostic Research Branch of the National Cancer Institute. He continued his work on complement but he felt driven to develop new approaches to the immunology of cancer. By inducing hepatomas in inbred guinea pigs with nitrosamines, he developed transplantable ascitic forms of these tumors appropriate for immunologic studies. Among these tumor lines was the famous line-10, which served for many of the pioneering studies by Herb and his many associates. His studies on the intralesional therapy of transplanted hepatomas with BCG, which showed that not only the primary but also lymph node metastases could be eradicated by this treatment, are now considered to be classic and have led to promising clinical trials in humans. His search for better models for immunotherapy of cancer led Herb to the application of nonliving BCG vaccines to naturally occurring carcinomas of large animals and, in the case of bovine ocular carcinoma, to spectacular results. He was in the midst of these studies when his life came to a tragic end.

During his career at the National Cancer Institute, Herb served on many committees where his insights into complex problems were often appreciated; he received the Superior Service Award of the National Institutes of Health in 1973; and for many years he served on the editorial boards of several journals including *Immunochemistry* (1969–72) and the *Journal of the National Cancer Institute* (1967–68).

Herb's greatest legacy survives in the colleagues who worked with him and in the younger associates who were trained by him. He taught them the importance of strict quantitation, of paying attention to the smallest detail, and of being supercritical of one's own work.

Many of us who knew Herb well and shared his working hours were also enriched by sharing many of his hours outside the laboratory. Strict adherence to time schedules led to the 11 a.m. exodus to the lunch table, where the conversation was free flowing, witty, and full of puns and jokes regardless of whether the discussion concerned science, politics, literature, his beloved music, or his other great loves: the ocean and fishing. While he could be generous with his wit and praise, he could be also a severe but just critic of the foibles of others as well as his own. Herb's death left us all poorer and we will miss him every day of our lives. Yet a small consolation remains: we were allowed to know him and be part of his life.

Human Lymphoma–Lymphoma Hybrids and Lymphoma–Leukemia Hybrids. I. Isolation, Characterization, Cell Surface Markers, and B-Cell Markers[1,2,3]

Jesper Zeuthen,[4] **George Klein,**[5] **Rosalie Ber,**[6] **Giuseppe Masucci,**[5] **Susanne Bisballe,**[4] **Susan Povey,**[7] **Paul Terasaki,**[8] *and* **Peter Ralph**[9,10]

ABSTRACT—Four new somatic cell hybrids were obtained by fusion of various Burkitt's lymphoma (BL)-derived cell lines that had different selective markers: Raji–P3HR-1, Daudi–Raji, and a P3HR-1–P3HR-1 "autohybrid" derived from two P3HR-1 sublines. In addition, a hybrid was obtained between the Daudi (BL) line and the human leukemia cell line K562. The hybrids were extensively characterized by means of chromosome, isozyme, and HLA surface markers. The phenotypic differences between the parent cell lines allowed some conclusions with respect to the expression of latent Epstein-Barr virus (EBV) genomes, C3 and EBV receptors, and of immunoglobulin and beta 2-microglobulin–HLA expression as well as the influence of the leukemia cell (K562) genome on B-cell properties in the Daudi–K562 hybrid. B-cell and differentiated markers of these hybrids were characterized. High-level expression dominated for the marker C3 and EBV receptors, which showed a good correlation coefficient of 0.84, as was true for Fc receptors and surface immunoglobulin. The Daudi–K562 hybrid showed loss of all B-cell markers but retention of the leukemia cell markers (e.g., hemoglobin synthesis).—JNCI 1982; 68:179–195.

When two human lymphoid cell lines of B-cell derivation are hybridized, a variety of B-cell markers (e.g., Fc, C3, and EBV receptors) show an autonomous, codominant pattern of expression as a rule, while some other markers (e.g., sIg) appear to be subject to more complex regulatory mechanisms (*1–3*). The derived hybrid cells might resemble either the more or less marker-expressing parental cell. The expression of differentiated functions can in contrast be completely autonomous in hybrids between closely related BL cell lines, in which two Ig light chains are coexpressed in approximately the same proportion as those produced by the original parental cells (*4*).

When BL-derived cells are fused with cells of other differentiation lineages, such as with epithelial cells or fibroblasts, the B-cell markers are extinguished in the fused cells (*5, 6*). This behavior is similar to what is known for most differentiation markers in various hybrid combinations in which differentiation programs are mutually exclusive and in which highly differentiated (or "luxury") functions are usually lost after hybridization (*7, 8*). An additional factor of importance for the expression of differentiation functions appears to be cell shape, which must be compatible with the expression of a certain program of differentiation (*9*). In hybrids between BL-derived cell lines, various levels of expression ranging from complete coexpression (*4*) to variable quantitative effects on the expression of various B-cell markers may be observed. These effects presumably reflect subtle differences in the differentiation programs involved. In a previous study of a hybrid of the BL-derived cell line P3HR-1 with the CML-derived K562 human leukemia cell

line, the markers of the K562 cell line were observed to dominate in this particular hybrid combination; one putative marker of B-cell differentiation, inducibility for EBV viral cycle antigens, was completely extinguished in this hybrid combination (*10*). This is of interest since K562 cells, reportedly established from a CML patient in blast crisis (*11*), would be assumed to share a common stem cell origin with human B-cells (*12*).

In the present report, we characterize five new somatic cell hybrids, four formed by fusion of BL-derived B-cell lines and one formed between the K562 cell line and a BL-derived line (Daudi), and present an analysis of their surface- and differentiation-related marker properties. An accompanying paper will report on the expression of EBV antigens in this hybrid panel (*13*).

MATERIALS AND METHODS

Cell lines.—The P3HR-1 line was derived from the established Jijoye cell line (*14*). The K562 cell line was derived from a CML patient in blast crisis (*11*) and contained an r(22) marker chromosome (*15*) derived from the original Ph^1 marker (*16*). The TG^r, $HPRT^-$ derivative of Daudi, DIT, previously described (*17*), was routinely grown in the presence of 50 µg TG/ml. The Raji TK^- subline RUD (*18*) was received from Dr. Berge Hampar (NCI Frederick Cancer Research Facility, Frederick, Md.) and grown routinely in the presence of 40 µg BrdUrd/ml. The two $ouab^r$ and TG^r sublines of P3HR-1 and Daudi, PUT and DUT, respectively, were derived from the $ouab^r$ sublines (*19*) by selection for resistance to TG at 50 µg TG/ml. The PUT subline has been described in more detail elsewhere (*10*). The CAP^r and TG^r subline of P3HR-1 was obtained after P3HR-1 was treated with 200 µg of the mutagen EMS/ml for 24 hours; then the TG concentration was increased stepwise to 50 µg TG/ml, and without further EMS exposure, treatment with 1,000 µg CAP/ml resulted in a doubly resistant (50 µg TG/ml, 1,000 µg CAP/ml) subline of P3HR-1, PICAT. P3HR-1 and RUD expired on 100 µg CAP/ml; K562 and RUD expired on 0.1 µ*M* ouab; all TG^r and $BrdUrd^r$ sublines expired on HAT medium. All lines were maintained in RPMI-1640 medium supplemented with 8% FCS and antibiotics (100 IU penicillin/ml, 50 µg streptomycin/ml), with additional supplements as mentioned above.

Cell hybridization.—All hybrids were obtained from cells fused with UV-inactivated Sendai virus, as described (*10*). After 24 hours, the medium was exchanged for HAT medium. For the fusions with PUT and DUT, the HAT medium was supplemented with 1 µ*M* ouab, which was later increased to 10 µ*M*. For the fusions with PICAT, the HAT medium was supplemented with 500 µg CAP/ml. Living cells were separated from dead cells during the hybrid selections by the Ficoll-Isopaque procedure (*20*). Vigorous hybrid growth commenced after 3–4 weeks, after which the first karyotyping was performed.

Chromosome analysis.—Cultures were harvested 1–2 days after subculture, following treatment with Colcemid. Cells were treated with 0.56% KCl for 8 minutes at room temperature, fixed three times, and spread on object slides. Preparations were stained with quinacrine mustard (*21*). For enumeration and more detailed analysis, the metaphases were photographed with a Zeiss photomicroscope that was equipped for fluorescence microscopy with an HB200 mercury light source, a KP500 excitation filter, an LP520 barrier filter, and an FT510 dichroic mirror. Photographic negatives were analyzed by projection (× 4,200), and karyotypes were compiled from photographic enlargements (× 2,400) and arranged according to the Paris Conference (*22*). The description of karyotypes follows the International System for Human Cytogenetic Nomenclature (*23*).

Isozyme analysis.—Cell pellets from parental cell lines and hybrid cells, each pellet containing about 10^7 cells, were used for enzyme analyses. Cells were lysed by freezing and thawing twice in a volume of distilled water approximately equal to that of the cell pellet. The resulting extract was subjected to horizontal starch gel electrophoresis and subsequent enzyme detection by the use of routine methods (*24*).

Cytotoxicity and absorption tests.—The assay for β_2m was by the cytotoxic absorption experiments as described in a previous study (*25*).

Quantitative immunofluorescence.—Cells were washed twice in medium and incubated with FITC-labeled rabbit anti-human β_2m (diluted 1:100; in some experiments, the reagent was Daudi absorbed and used at 1:16), with FITC-labeled rabbit anti-human Ig (1:20), anti-11 IgM (1:15), or with anti-11 κ-chains (1:10) (DAKO-immunoglobulins Ltd., Copenhagen, Denmark) for 30 minutes at 4°C, washed twice, and analyzed in a FACS (FACS III; Becton, Dickinson Electronics Lab., Mountain View, Calif.). CMIF staining was performed as described (*26*). This procedure leads to C3 activation by the cells with subsequent binding of activated C3 to preformed receptors (*27*). After this treatment, the cells were washed twice and similarly analyzed in the FACS III. The results were analyzed by a computer program (Klein, Gunnar: Unpublished program). To correct for nonspecific fluorescence, we defined a "cut level" to include 95% of negative control cells. The results were calculated as the following expressions of relative fluorescence of the cells analyzed: Mean = mean of all determinations/mean of values above cut level, percent positive cells = cells above cut level, and total fluorescence index = arbitrary value representing the area corresponding to cells above cut level.

HLA antigens.—Standard microlymphocyte cytotoxicity was used to determine the HLA antigens of the cells studied. The complement used for the hybrids and their parental lines was absorbed with 40×10^6 pooled lymphoblastoid cells/ml. High-titer HLA antisera diluted to a minimum of 4 cytotoxic U were absorbed with 100 and 20×10^6 cells/ml of antiserum during a 1 hour incubation at 4°C. The cell suspensions were centrifuged, and titrations (double dilutions) of the supernatants were tested for cytotoxicity with lymphocytes positive for the relevant HLA antigen. HLA antisera negative for the cells used for absorption served as the specificity controls. The absorptions were considered positive when the titer of the absorbed antiserum was reduced twofold compared to unabsorbed antisera, after the values for the nonspecific absorption controls were subtracted.

Rosette tests.—For C3 receptors, EAC rosettes were detected as described (*28*). For Fc receptors, sheep RBC were sensitized with rabbit IgG, as described (*29*). For sIg, *Staphylococcus aureus* protein A-coupled RBC rosettes were detected by polyvalent rabbit anti-human Ig. For Ia-like antigens, *S. aureus* protein A-coupled RBC rosettes were detected by rabbit anti-human Ia (Alpha Gamma Laboratories, Sierra Madre, Calif.). Target cells that bound at least three erythrocytes were scored positive in all rosette tests. Cell lines were scored negative when less than 3% formed rosettes.

EBV receptors.—EBV receptors were measured by a modification of the bioassay of Sairenji and Hinuma (*30*), as described in (*31*). An EBV-containing P3HR-1 cell supernatant was used as the virus source in a final dilution of 1:5; the unabsorbed supernatant induced 10–15% early antigen in Raji cells after 48 hours. After absorption with graded numbers of parental and hybrid cells, the residual supernatant was tested for its ability to induce early antigen in Raji cells after 48 hours. Standard EBV receptor-positive (Raji) and EBV receptor-negative (YAC-1) controls were included in each test. The AI was calculated as follows: AI = (maximum percent early antigen induced by unabsorbed control cells−maximum percent early antigen induced by absorbed test cells)/maximum percent early antigen induced by unabsorbed control cells.

Other markers.—*β*-Glucuronidase was assayed in 1% Nonidet P40 cell lysates in which phenolphthalein glucuronic acid was used as a substrate (kit No. 325; Sigma Chemical Co., St. Louis, Mo.). Cell culture supernatants contained less than 0.1 U *β*-glucuronidase/ml at 10^6 cells/ml. Lysozyme was determined turbidimetrically (*32*) and expressed as microgram equivalents of egg lysozyme per 10^6 cells/ml in 24-hour culture supernatants. Extracts contained less than 0.01 µg lysozyme/10^6 cells.

Incorporation of ^{59}Fe by whole cells, as assayed in extracted heme, was determined after incubation of 10-ml cultures with ^{59}Fe (ferrous citrate: 10 µCi/ml, 13.93 µCi/ng; New England Nuclear Corp., Boston, Mass.). Cultures were seeded at 5×10^4 cells/ml and analyzed at day 6. The counts in whole cells and in methyl ethyl ketone-extracted heme, after cleavage of hemoglobin into heme plus globin, was determined by a scintillation counter and expressed as picomoles ^{59}Fe incorporated per 10^5 cells (*33*). Percentages of hemoglobin-positive cells were estimated from cell slides stained with benzidine (*34*).

RESULTS

Derivation of Variant and Hybrid Cells

The five new somatic cell hybrids characterized in the present paper were isolated after fusion of the parental cells, which was induced by UV-inactivated Sendai virus. To facilitate the designation of the hybrid cells, we used the following *abbreviated designations* for the parental cells and their hybrids: The BrdUrd^r, TK$^-$ subline of Raji was designated RUD (*18*). The TG^r, HPRT$^-$ subline of Daudi was designated DIT (*17*). The ouab^r and TG^r (HPRT$^-$) subline of P3HR-1 was designated PUT (*10*). Cell lines lacking selective markers were K562 (*11*) (designated KO) and P3HR-1 (*14*) (designated PO). New variant sublines isolated in the course of the present study were the CAP^r and TG^r (HPRT$^-$) subline of P3HR-1 (designated PICAT) and the ouab^r and TG^r (HPRT$^-$) subline of Daudi (designated DUT).

The double variants containing one recessive (HPRT$^-$) and one dominant (ouab^r or CAP^r) marker permitted the isolation of hybrids from other cell lines carrying no such selective markers when grown in HAT medium supplemented with either ouab or CAP. We used this approach to isolate the DUT × K562 (DUTKO-1) and PICAT × P3HR-1 (PICATPO-1) hybrids. The double variants PUT and PICAT were hybridized with RUD, and double-selective systems (HAT medium with either ouab or CAP) were used to isolate the RUDPUT-2 and RUDPICAT-1 hybrids. In addition, a new Daudi–Raji hybrid was isolated when the standard HAT-medium selection process was used (DIT × RUD = DITRUD-1). The derivation of these somatic cell hybrids is summarized in table 1.

Chromosomal Characterization

RUDPUT-2 and RUDPICAT-1 Hybrids

The RUD parental cell line carried a number of specific markers. Three characteristic markers (4q+, 11q+, and 14q+) were derived from the t(8;14) translocation in BL

TABLE 1.—*Derivation of parental and hybrid cells*

Parental cells				Hybrid cells	Selection method
Cell line (derivation)	Markers (drug resistance)	Designation	Reference		
Raji (BL)	TK$^-$ (BrdUrd^r)	RUD	(*26*)	RUDPUT-2	HAT medium + ouab
P3HR-1 (BL)	ouab^{r}HPRT$^-$ (TG^r)	PUT	(*10*)		
Raji (BL)	TK$^-$ (BrdUrd^r)	RUD	(*26*)	RUDPICAT-1	HAT medium + CAP
P3HR-1 (BL)	CAP^{r}HPRT$^-$ (TG^r)	PICAT	This article		
Daudi (BL)	HRPT$^-$ (TG^r)	DIT	(*25*)	DITRUD-1	HAT medium
Raji (BL)	TK$^-$ (BrdUrd^r)	RUD	(*26*)		
Daudi (BL)	ouab^{r}HPRT$^-$ (TG^r)	DUT	This article	DUTKO-1	HAT medium + ouab
K562 (CML)	None	KO	(*11*)		
P3HR-1 (BL)	CAP^{r}HPRT$^-$ (TG^r)	PICAT	This article	PICATPO-1	HAT medium + CAP
P3HR-1[a] (BL)	None	PO	(*22*)		

[a] P3HR-1 was derived from the cell line Jijoye.

cells, which included Raji (*35*). These markers have also been found in other Raji sublines (*36*). In addition, the RUD line carried two translocation chromosomes in which chromosome 17 was involved. RUD translocations were designated as t(17;?)(q25;?) and t(17;?)(q24;?). The karyotype of RUD can thus be described as 46,XY,4q+,11q+, 14q+,t(17;?)(q25;?),t(17;?)(q24;?).

The karyotype of PUT was similar to that previously described (*10*), with the karyotype 48,XY,+large metacentric chromosome,+small metacentric chromosome,14q+. The karyotype of the PICAT subline indicated two types of cells with different karyotypes and containing a small metacentric marker (similar to the corresponding marker in PUT), a submetacentric marker, and a new characteristic isochromosome of the short arm of X, i(Xp). In approximately 60% of the cells, an additional marker presumably derived from the i(Xp) appeared, resulting in an increase in chromosome number from 48 to 49. The karyotype of the population of PICAT cells may therefore be represented as 48,Y,i(Xp),+small metacentric chromosome,+submetacentric chromosome/49,Y,i(Xp),?i(Xp),+small metacentric chromosome,+submetacentric chromosome.

The RUDPUT-2 hybrid cells, isolated approximately 1 month after fusion of the parental cells, had a modal chromosome number of 94, which was expected from the summation of the parental RUD and PUT modal chromosome numbers (46+48=94). The markers of the two parents were represented in very high frequency in the metaphases analyzed (table 2). Two characteristic new markers, 13q+ and Yp+, were present in all RUDPUT-2 hybrid metaphases. Some metaphases appeared to have lost the small metacentric marker of PUT. A representative karyotype of RUDPUT-2 is shown in figure 1. The karyotype can be represented as 94,XXY,Yp+,+large metacentric chromosome,+small metacentric chromosome,4q+,11q+,13q+, 14q+,14q+,t(17;?)(q25;?),t(17;?)(q24;?).

The RUDPICAT-1 hybrid cells were similarly isolated about 1 month after fusion of RUD with PICAT. The RUDPICAT-1 hybrid cells had a modal chromosome number of 94, which was similar to that of RUDPUT-1, but a few cells with 95 chromosomes were also found. Most hybrid cells appeared to be derived from the fusion of RUD with PICAT cells containing 48 chromosomes, and the modal number of 94 chromosomes in RUDPICAT-1 therefore corresponded to what is expected from the summation of the parental chromosome numbers (46+48=94). The markers of RUD were recognized in most metaphases, though the RUD-derived 14q+ marker was lost in most metaphases. A lower proportion of PICAT markers was recognized in the RUDPICAT-1 hybrid metaphases, and

TABLE 2.—*Chromosome markers in metaphase karyotypes of parent and hybrid cells*

Hybrid cells	Cells tested (No. of metaphases)	Presence of marker, % of metaphases[a]												
										New				
		4q+	11q+	14q+	17q+[b]	17q+[c]	14q+	LMC	SMC	13q+	Yp+

[c] t(17;?)(q24;?).

[d] del(15)(q14q21).

[e] Metaphases had *two* 14q+ markers identified.

[f] Cell line is K562 lacking selective markers.

[g] Cell line is P3HR-1 lacking selective markers.

two PICAT markers, ?i(Xp) and a small metacentric marker, were not found in any of the metaphases analyzed (table 2). In a small fraction of metaphases, an additional chromosome 16 was present. A representative karyotype of RUDPICAT-1 is shown in figure 1. The karyotype can be represented as 94,XYY,i(Xp),+submetacentric chromosome,+16,4q+,11q+,14q+,t(17;?)(q25;?),t(17;?)(q24;?).

DITRUD-1 Hybrid

The karyotype of DIT (Daudi-TG) was found to be identical to that previously published (*17*): 46,XY,14q+, del(15)(q14q21). The 14q+ marker, presumably derived from the BL t(8;14) translocation, was found in 100% of the cells analyzed. The specific interstitial deletion of one chromosome 15, del(15)(q14q21), was also found in other Daudi cell lines, also completely deficient in β_2m production (*37*). The standard locus for β_2m was assigned to the affected region of chromosome 15 (*38–40*).

The DITRUD-1 hybrid contained markers from both of its parents, DIT and RUD. Several months after selection, it had a modal chromosome number of 92, as expected from the summation of the parental cell modal number (46+46=92). The markers of the two parents were represented in the hybrid metaphases, as described in table 2. A few additional new markers were observed in some metaphases like the one illustrated in figure 2, in which the karyotype was 91,XXYY,+submetacentric chromosome,+acrocentric chromosome,−14,−16,−17,t(i(1q);?)(q36;?),4q+,11q+,14q+,14q+,del(15)(q14q21),t(17;?)(q24;?),t(17;?)(q25;?).

DUTKO-1 Hybrid

The karyotype of K562 (a cloned subline) was identical with that previously described (*10*) [69,XXX,+7,+9(p11),+small metacentric chromosome,−13,−17,−21,del(X)(p21), del(3)(p11),del(9)(p11),15q−, 18q+,r(22)], with loss of one chromosome 21 as the only difference from cultures studied 5 years ago (*15*). The karyotype of DUT was 47,XY,+7, 3q+,14q+,del(15)(q14q21). A deviation from the typical minimal deviation karyotype of Daudi was observed in this case. The gain of an extra chromosome 7, as found here, is a common observation during long-term cultivation of diploid lymphoblastoid cell lines.

The modal chromosome number of DUTKO-1 hybrid was 113, as determined several months after its selection. This is only two chromosomes less than the expected number (46+69=115). The marker chromosomes are indicated in table 2. In addition to the parental markers, two new submetacentric markers appeared in the DUTKO-1 hybrid. A representative karyotype is shown in figure 3: 113,XXXY,del(X)(p21),+2,+7,+small metacentric chromosome,+submetacentric chromosome,+large submetacentric chromosome,−4,−6,−6,−13,−17,−18,−21,−22,del(3)(p11),csb(9)(p11),del(9)(p11),15q−,18q+,r(22),14q+,del(15)(q14q21).

PICATPO-1 Hybrid

A P3HR-1 subline was hybridized with the PICAT variant, also derived from the parental P3HR-1 line, and therefore should represent a hybrid formed by the fusion of two P3HR-1 sublines. The parental, unmarked P3HR-1 subline (PO) used for hybridization was of the karyotype 48,XY,+11,+large metacentric chromosome,14q+. The karyotype of PICAT was identical to that described previously [48,Y,i(Xp),+small metacentric chromosome,+submetacentric chromosome/49,Y,i(Xp),?i(Xp),+small metacentric chromosome,+submetacentric chromosome]. The 14q+ marker was scored in only a low percentage of metaphases from PICAT, even in metaphases with quality good enough to discount the lack of detection for technical reasons; we therefore suggest that part of the population lost its 14q+ marker during cultivation.

Inasmuch as the two P3HR-1 sublines showed identical isozyme profiles, the detailed chromosomal characterization was particularly important for the characterization of the PICATPO-1 hybrid, because tetraploid cells arise rather frequently in cultures of BL cells. The PICATPO-1 hybrid cells, isolated approximately 1 month after fusion, had a modal chromosome number of 96, as expected (48+48=96); however, some cells corresponding to the karyotype indicated in figure 4 had 97 chromosomes. The karyotype (fig. 4) is 97,XYY,i(Xp),?i(Xp),+11,+small metacentric chromosome,+submetacentric chromosome,+large metacentric chromosome,14q+. Most metaphases contained only one 14q+ marker chromosome, in agreement with the apparent loss of this marker in most metaphases of the PICAT parent. The presence of the PICAT-derived markers [i(Xp),?i(Xp), small metacentric chromosome,submetacentric chromosome] in addition to the PO markers (+11,large metacentric chromosome) identifies the PICATPO-1 line as a true hybrid (table 2).

Isozyme Analyses

The parental and hybrid lines were tested for a number of marker enzymes previously found useful in cell identification (*41*) as well as for some additional enzymes (table 3). For the RUDPUT-2 and RUDPICAT-1 hybrids, four loci were informative: that for phosphoglucomutase 3 (*PGM3*), for glyoxalase I (*GLO*), for adenine phosphoribosyltransferase (*APRT*), and for peptidase A (*PEPA*). Glyoxalase I, a dimeric enzyme, provided good confirmation of the hybrid origin of the cells since RUD was type 2 and the P3HR-1 sublines were type 1 (table 3). DITRUD-1 was confirmed to be a hybrid by two informative loci: that for glucose-6-phosphate dehydrogenase (*G6PD*) and that for phosphoglucomutase 3 (*PGM3*). In addition, the parents of DITRUD-1 were abnormal in respect to expression of lysosomal hexosaminidases A and B [*HEXA* and *HEXB* (*42*)], and these defects were not complemented in the hybrid (table 3). For DUTKO-1 the following loci were informative: *PGM3*, *G6PD*, and that for phosphoglucomutase 1, *PGM1*, where the deficiency of K562 was complemented (table 3).

ME1 was absent in all BL cell lines tested but was present in K562; this enzyme was also expressed by DUTKO-1 (table 3). Further studies (*43*) indicate that this particular enzyme deficiency is a marker for the differentiation of malignant lymphoma and leukemia cells.

GLO	6	2	2	1	1	1	2	2-1	2-1	NT	2

[a] By starch gel electrophoresis, 0=absent, 1=type 1, and 2=type 2. For APRT, x=variant; for G6PD, A=type A and B=type B. NT=not tested.

[b] A trace of enzyme was possibly present.

[c] Activity was very weak; cells could possibly have a trace of phosphoglucomutase 3-1.

Absorption Experiments

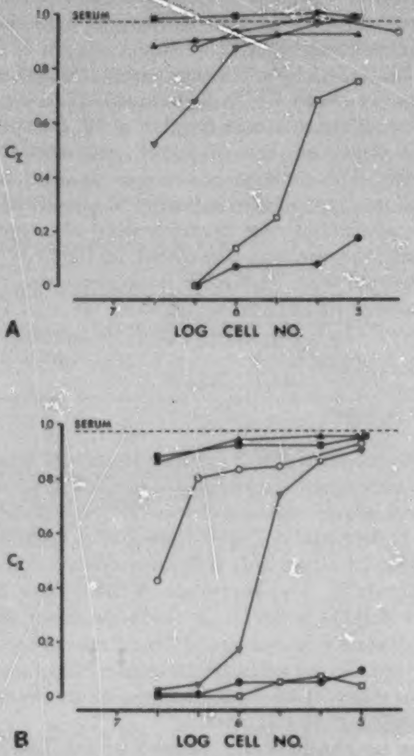
Rabbit anti-human β_2m antiserum, diluted 1:20, gave a cytotoxicity index between 0.80 and 0.95 against target P3HR-1 cells in various experiments. Text-figure 1 shows the results of absorptions performed with intact living cells and the corresponding absorptions made with lysates from frozen–thawed cells.

The β_2m-negative Daudi line absorbed no anti-β_2m in contrast to the positive control Raji cell line. The DITRUD-1 hybrid absorbed more than Raji, showing that the lack of β_2m is complemented after fusion of Daudi with Raji. Similar results were found with frozen–thawed cells. Living DUTKO-1 hybrid cells and their K562 parent absorbed anti-β_2m weakly. The corresponding experiment with frozen–thawed cells gave weak absorption for K562 and a somewhat increased absorption with DUTKO-1. The intermediate concentrations of β_2m of P3HR-1 found here correspond to the concentrations in the two sublines PUT and PICAT. The expression of β_2m by the DUTKO-1 hybrid was similar to that previously observed for the P3HR-1–K562 (PUTKO-1) hybrid (*10*).

Quantitative Immunofluorescence

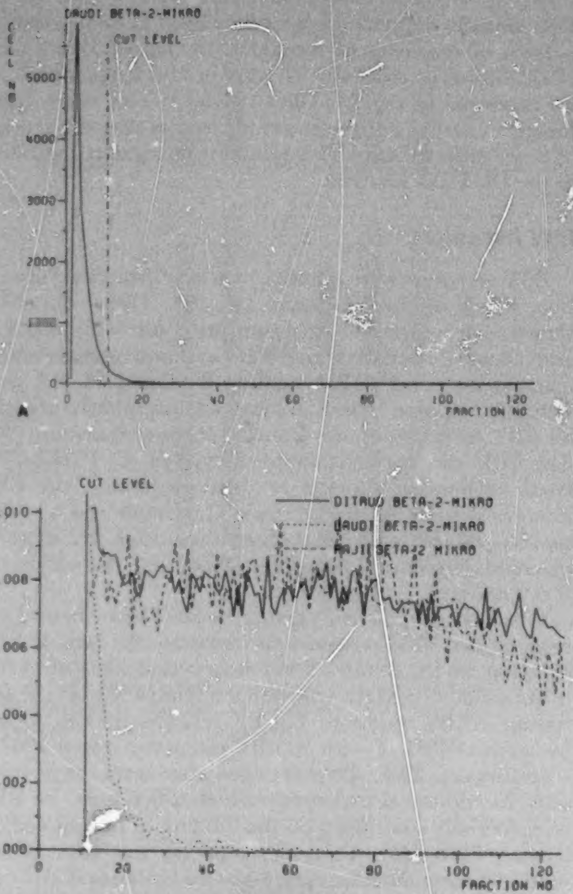
Immunofluorescence staining of living cells was performed with an FITC-conjugated rabbit anti-human β_2m antiserum diluted 1:100. The membrane immunofluorescence-stained cells were analyzed in flow fluorimetry in a FACS cell sorter, and the distributions of fluorescence intensity were evaluated and plotted by means of a computer program. We defined our parameters in "Materials and Methods."

An example of this analysis performed on Daudi cells is given in text-figure 2. The DITRUD-1 hybrid showed complete expression of β_2m (text-fig. 2). A slight increase in fluorescence intensity was noted in the measurements on DUTKO-1 and its parents in the standard immunofluorescence analysis. However, it was not possible from these results to evaluate whether the increase was due to nonspecific fluorescence. For more precise estimation of DUTKO-1 β_2m expression, the immunofluorescence analysis was repeated with a less dilute (1:16) Daudi-absorbed rabbit anti-human β_2m reagent. In this series of experiments, the DUTKO-1 hybrid had markedly increased β_2m fluorescence compared to that of the two parental cell lines. The results from the quantitative analyses for β_2m are summarized in table 4.



TEXT-FIGURE 1.—Quantitative absorption for β_2m with A) intact living cells and B) frozen–thawed cells. Rabbit anti-human β_2m serum was used at a dilution of 1:20. The cytotoxicity index (C_I) of the unabsorbed serum is indicated by ----. ▲=K562 (KO); ○=DUTKO-1; ■=Daudi; ▽=P3HR-1; □=Raji; ●=DITRUD-1.

A similar analysis was done for sIg expression. An example of the results for the DITRUD-1 hybrid is given in text-figure 3. The Daudi and Raji parental cells expressed very different levels of sIg (IgM κ-chain): Daudi expressed very high levels while Raji was almost negative. The DITRUD-



TEXT-FIGURE 2.—Quantitative immunofluorescence analysis of cells stained for surface β_2m (BETA-2-MIKRO) with an FITC-conjugated rabbit anti-human β_2m serum at a dilution of 1:100 and analyzed in the FACS. A) Analysis of β_2m-negative Daudi cells. The cut level, which includes 95% of the known negative cells, is indicated by ----. B) Analysis of the DITRUD-1 hybrid (DITRUD) and its two parents (RAJI and DAUDI). The Raji parents are β_2m-positive, as is the equally positive hybrid.

1 hybrid expressed intermediate sIg fluorescence as compared to the highly positive Daudi cell line. The DUTKO-1 hybrid showed an absolute suppression of sIgM, indicating extinction of this B-cell marker. The two Raji–P3HR-1 hybrids (RUDPUT-2 and RUDPICAT-1) were also analyzed for sIg; here, the relatively stronger expression of P3HR-1 dominated in the hybrids. The results of analyses of sIg expression are summarized in table 4.

HLA Antigens

The presence of HLA antigens was analyzed by complement-mediated cytotoxicity by the use of 1980 Workshop antisera (*44*). The P3HR-1 sublines PUT and PICAT were HLA-positive (A3;B17,w4;Cw4), although the detection of the third locus antigen (Cw4) was doubtful in PICAT. The RUD parent was positive for HLA-A3; Bw6;Cw3,w4. No HLA-A,B,C antigens were found on the DUT parental line in accordance with our previous data for Daudi cells (*25, 45*). The K562 cell line was negative for HLA-A,B,C and Ia-like antigens in accordance with previous results (*10*). The results of HLA typing of the parental cells and hybrids are summarized in table 5.

Since the DITRUD-1 hybrid was observed to express normal levels of β_2m, we assumed, analogous to our previous results showing complementation of the β_2m deficiency of Daudi cells and leading to re-expression of "hidden" HLA specificities in hybrids (*25, 45*), that this situation would be true also for the DITRUD-1 hybrid. The DITRUD-1 hybrid carried all the specificities except Cw4 of RUD; in addition the following new specificities were re-expressed: A26 (part of A10);B17,w4. No HLA antigen specificities were detected on DUTKO-1 and either of its two parents (DUT and K562) when standard cytotoxicity was measured.

Since the PUTKO-1 hybrid (*10*) was observed to express very low, subcytotoxic concentrations of the P3HR-1-derived specificity HLA-A3 by the relatively more sensitive absorption test, this test was used in an attempt to detect a low level of re-expression of the Daudi-derived hidden HLA specificities A26 and B17. An anti-B17 serum was absorbed by DUTKO-1 cells at 100×10^6 cells/ml, but at 20×10^6 cells/ml, absorption was doubtful. Anti-A26 serum and anti-B12 serum (anti-B12 was used as a specificity control) were not absorbed at either of the two cell concentrations. These results indicate that the observed complementation with respect to β_2m expression leads to re-expression of HLA.

TABLE 4.—*Quantitative immunofluorescence of surface β_2m and Ig*

Cells tested	Surface globulin	Parameters			
		Cut level	Mean[a]	Percent positive cells	Total fluorescence index
DITRUD-1[b]	β_2m	11	55.6	87.7	48.8

DUTKO-1[c]	β_2m	49	*81.7*	40.9	33.4
K562	β_2m	49	*72.7*	16.4	11.9
Daudi	β_2m	49	*81.0*	4.9	4.0
DITRUD-1[d]	IgM	11	20.1	68.7	13.8
Raji	IgM	11	13.2	3.9	0.52
Daudi	IgM	11	21.7	79.5	17.3
DITRUD-1[e]	κ-chains	11	23.5	70.9	16.7
Raji	κ-chains	11	15.0	2.0	0.3
Daudi	κ-chains	11	41.5	82.9	34.2
8A[d]	IgM	17	10.2	16.1	1.64
Raji	IgM	17	6.0	4.8	0.29
Daudi	IgM	17	29.4	60.7	17.9
RUDPUT-2[f]	Ig	14	*29.5*	26.8	7.9
Raji	Ig	14	*24.2*	2.9	0.7
PUT	Ig	14	*27.8*	4.5	1.3
RUDPICAT-1[f]	Ig	14	*30.1*	16.0	4.8
Raji	Ig	14	*24.2*	2.9	0.7
PICAT	Ig	14	*38.8*	10.7	4.1

[a] Mean is of all values; *italicized* mean is the mean of values that exceeds the cut level (arbitrary units).

[b] Cells were tested with anti-β_2m at 1:100.

[c] Cells were tested with Daudi-adsorbed anti-β_2m at 1:16.

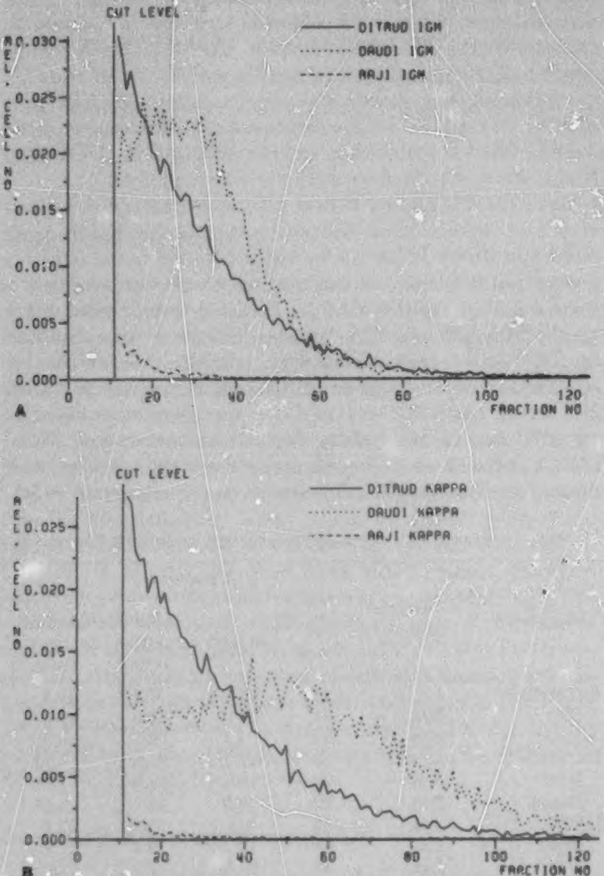
[d] Cells were tested with anti-IgM at 1:15.

[e] Cells were tested with anti-κ at 1:10.

[f] Cells were tested with anti-Ig at 1:20.

The reason that only one specificity (that of B17) was found to be re-expressed could be that this particular specificity competes more efficiently for the very limited amounts of β_2m available on the cell surface than does A26.

The DUTKO-1 hybrid and its two parents were also analyzed by the use of typing sera against Ia-like (HLA-DR) antigens for cytotoxicity. While DUT showed a similar pattern of reactivity as compared to that of Daudi, and K562 showed no reactivity whatsoever, this Ia reactivity was *not* expressed in the DUTKO-1 hybrid. This result (confirmed by Ia-like antigen rosetting) argues that this marker of B-cell differentiation, in addition to sIg, was extinguished in the DUTKO-1 hybrid.



TEXT-FIGURE 3.—Quantitative immunofluorescence analysis of cells stained for sIg and analyzed in the FACS. The DITRUD-1 hybrid (DITRUD) and its two parents (RAJI and DAUDI) were stained for A) sIgM (IGM) with FITC-conjugated rabbit anti-human IgM at a dilution of 1:15 and for B) κ-chains (KAPPA) with FITC-conjugated anti-human κ-chains at a dilution of 1:10. The cut level excludes 95% of Raji cells.

EBV Receptors

EBV receptors were assessed by a modified virus absorption, infectious virus bioassay (*30, 31*). These results are shown in text-figure 4. As shown previously (25), the Raji and Daudi lines had a high EBV-receptor concentration, whereas the two P3HR-1 sublines PUT and PICAT were virtually negative. The K562 line was completely negative for EBV receptors, as also found in our previous study (*10*). The EBV receptor-negative phenotype of the P3HR-1-derived sublines in contrast to their progenitor, the EBV receptor-positive BL line Jijoye (*14*), is explained by selection in culture; whereas the negativity of K562 must be regarded as a natural property of K562 cells, which are not B-cell derived.

Like its negative K562 parent, the DUTKO-1 hybrid was negative for EBV receptors. In contrast, the lack of EBV receptors in PUT and PICAT was complemented by hybridization with RUD, which had a relatively high concentration of EBV receptors. The PICATPO-1 hybrid, derived by fusion of PICAT with an EBV receptor-negative P3HR-1 subline, was EBV receptor-negative, as were the parental cells. In additional experiments, a modified assay for EBV receptors was used based on the binding of [^{3}H]thymidine-labeled EBV (*46*). This very sensitive test gave similar results to those of the standard absorption assay.

Complement Receptors

For CMIF staining of C3, target cells were exposed to human complement (from EBV-negative donor serum) and were then stained with FITC-conjugated anti-human C3 (*26*). The data from the combined CMF and EAC analyses of the parent and hybrid cells are shown in table 6.

In contrast to the Raji and Daudi cell lines, which were highly positive for C3 receptors, P3HR-1 and its sublines PUT and PICAT were virtually negative. The three hybrids RUDPUT-2, RUDPICAT-1, and DITRUD-1 were intermediate between their parents. PICATPO-1 was higher

TABLE 5.—*HLA specificities detected by complement-mediated cytotoxicity*[a]

PICATPO-1	NT	5.7	34
DITRUD-1	NT	NT	48
DUTKO-1	TR	NT	25
PUTKO-1	TR	NT	12

[a] NT=not tested; TR=all cells showed a trace of positive reactivity.

[b] Percentages were determined by fluorescence microscopy.

[c] Arbitrary values were derived from quantitative analysis in the FACS.

than both parents, as judged from EAC rosetting. K562, DUTKO-1, and PUTKO-1 were weakly stained in the CMIF reaction and also gave a low frequency of EAC rosettes.

A close steric relationship has been established between the EBV and C3 receptors (*26, 47*). In the present data, there is a strong correlation between these parameters, as estimated by EBV absorption and by EAC rosetting. The plot of percent EAC rosettes against the EBV AI for the various cell lines and hybrids (text-fig. 5) shows a good correlation (r=0.84).

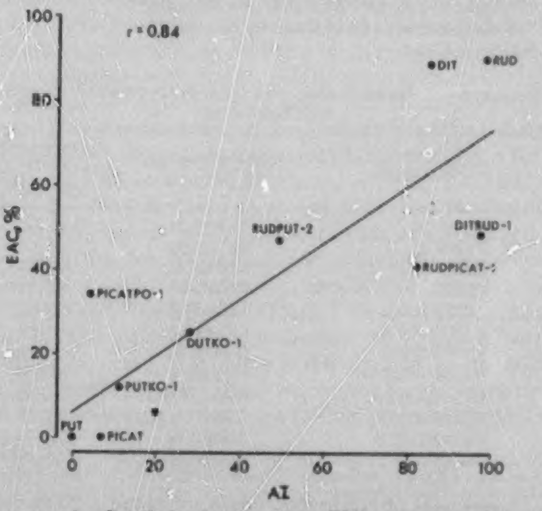
Rosette Tests for Surface Markers

Table 7 summarizes results for Fc receptors detected by EA rosettes (rabbit IgG antibody-coated sheep RBC), for sIg detected by *S. aureus* protein A-coupled RBC rosettes (polyvalent anti-human Ig), and for Ia-like (DR) antigens detected by *S. aureus* protein A-coupled RBC rosettes (rabbit anti-human Ia reagent).

The K562 cell line was characterized by a high percentage of EA rosette-positive cells, confirming previous results (*15*). In spite of the presence of Fc receptors, K562 was not capable of phagocytosing or lysing antibody-coated cells. RUD, DUT, P3HR-1, and its two sublines PUT and PICAT were negative for Fc receptors. Fc receptors were clearly amplified in the hybrids RUDPUT-2, RUDPICAT-1, and PICATPO-1, since these were all positive in the rosette tests (30% rosettes) compared to their respective parental lines. The DUTKO-1 line resembled its parental K562 line.

K562 was negative for B-cell markers like sIg and Ia-like (DR) antigens. The DUT line expressed high levels of sIg (IgM) and Ia-like antigen. Both of these markers were completely extinguished in the DUTKO-1 and PUTKO-1 hybrids. The Raji subline RUD showed a low but definite sIg expression in the rosette test and also showed a high level of Ia. The results for the various P3HR-1 sublines varied. PUT was negative for sIg, whereas P3HR-1 and PICAT both contained 16–17% positive cells. The PICATPO-1 cell line showed a surprisingly strong expression of Ia compared to that of its parents.

The RUDPUT-2 and RUDPICAT-1 hybrids exhibited dominance of the high levels of Ia expression characteristic of RUD, but the low levels of sIg expressed were similar to those of the parent cells. For DITRUD-1, the rosette tests confirmed the dominance of sIg expression observed previ-



TEXT-FIGURE 5.—Correlation between mean EBV receptor concentration (expressed by AI for 10×10^6 cells) and C3 receptors (determined as percent EAC rosettes) in the present panel of hybrid and parental cells. r=0.84, P<0.01.

ously. Ia-like antigens were expressed at levels similar to the high levels characteristic of the RUD parent.

Markers of Myeloid and Erythroid Differentiation

K562 contained high levels of β-glucuronidase and secreted lysozyme at high levels (table 8), as would be expected for cells related to the myeloid or monocytoid lineage. In contrast to the other BL lines tested here, the Daudi-derived DUT line expressed high levels of β-glucuronidase. None of the BL lines tested secreted lysozyme. The DUTKO-1 and PUTKO-1 hybrids had high levels of β-glucuronidase and secreted lysozyme, indicating dominance of the K562 phenotype (table 8).

K562 shows several of the properties of erythroid cells (48–52). One property is induction of hemoglobin synthesis by the inducer hemin (*50*). We compared K562, DUT, and the DUTKO-1 hybrid with respect to the levels of ^{59}Fe incorporated into extracted heme in the presence or absence of hemin, as well as compared the induction of benzidine-positive cells in the presence of this inducer. The ^{59}Fe incorporated into the extracted heme was significantly higher in K562 than in DUT. In the presence of hemin, the levels for K562 were increased more than twice. The DUTKO-1 hybrid had approximately twice the amounts of ^{59}Fe incorporated into heme as did K562, and this level was further increased after hemin induction (table 9). Similar results were obtained for the PUTKO-1 hybrid. Benzidine-positive cells appeared after 1 day and increased to about 90% after 5 days in the presence of hemin (text-fig. 6) in cultures of K562 and DUTKO-1. The PUTKO-1 hybrid gave similar results.

TABLE 7.—*Rosette tests for surface markers on parent and hybrid cells*

Cells tested	Receptor-positive cells,[a] %		
	Fc[b]	sIg	Ia

PUTKO-1	0.77±0.11	0.19±0.02

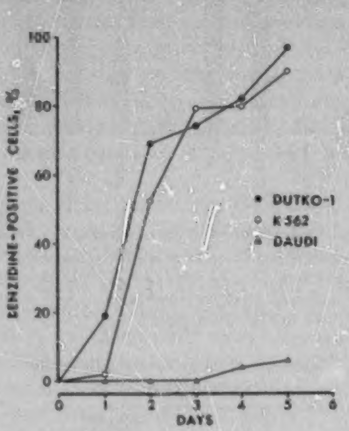
[a] Assays were of cell lysates. Values are means ± SEM. Culture supernatants contained 10^6 cells/ml.

[b] Assays were of 24-hr culture supernatants. Values are means ± SEM, expressed as microgram equivalents of egg lysozyme/10^6 cells/ml. Extracts contained <0.01 U/10^6 cells.

TABLE 9.—*Incorporation of ^{59}Fe in whole cells and into extracted heme*

Cells tested	^{59}Fe content[a]	
	Whole cells	Extracted heme
DUT		
Untreated	10.15	0.032
Hemin treated	19.11	0.026
K562		
Untreated	27.52	0.23
Hemin treated	87.10	0.45
DUTKO-1		
Untreated	46.49	0.46
Hemin treated	178.81	0.95

[a] Content was measured on day 6 as picomoles ^{59}Fe incorporated/10^5 cells that had been seeded without or with 0.1 m*M* hemin.



TEXT-FIGURE 6.—Induction of benzidine-positive cells in the presence of 0.1 m*M* hemin.

DISCUSSION

Previous work with hybrids between human hematopoietic cells (*1–6, 10, 15, 17*) has demonstrated a relatively high degree of stability for such hybrids with respect to chromosome, isozyme, and phenotype markers. This agrees with the evidence presented in this paper and argues well for the use of such hybrids in studies in which differentiation-related mechanisms of hybrid cells are examined, which at present is one of the few ways by which such an analysis can be achieved. A more analytical approach would be the use of hybrids of this type for targeted selection experiments against single phenotypic traits when the fate of additional markers are followed.

The results presented here extend and complement our previous studies (*1–6, 10, 15, 17*). Similarly, as in our previous work, we could unequivocally identify hybrids by the chromosome marker analysis described here. In one situation, that of the "autohybrid" (PICATPO-1) formed by the fusion of two P3HR-1 sublines, this approach was found useful for hybrid identification in a situation when other means of identification (e.g., HLA, isozymes) would have been uninformative.

As expected, HLA was coexpressed in the hybrids examined. Two hybrids are of special interest as regards HLA expression: The characteristic lack of β_2m in the Daudi line (*25, 37*) was fully complemented in the Daudi–Raji (DITRUD-1) hybrid, with resulting re-expression of new HLA-A,B specificities (A26 and B17), thus confirming previous data (*25, 45*). As shown previously (*37*), the K562 cell line was deficient in membrane-expressed β_2m but did contain intracellular β_2m. This membrane defect of K562 has been previously observed to be partially dominant in the P3HR-1-K562 hybrid PUTKO-1 (*10*), since only one P3HR-1-derived specificity (HLA-A3) was detected in low amounts on the surface of this hybrid line. The hybrid between Daudi and K562 (DUTKO-1) described here is therefore derived from two phenotypically different β_2m-deficient lines, and genetic complementation could be expected, as demonstrated here by the re-expression of low amounts of the Daudi-derived specificity HLA-B17.

Isozymes were also coexpressed in the hybrid lines in confirmation of their hybrid derivation. In the present and additional studies (*43*), the enzyme *ME1* was found to be absent from all BL-derived cell lines and their hybrids as well as from other cells of lymphoreticular, malignant origin. The parent K562 cell line and its two hybrid lines generated with BL cells expressed *ME1*, in line with the dominance of the K562 phenotype in these hybrids. That this effect could be related to the more primitive phenotype of K562 is suggested by the observation that human *ME1* is re-expressed in hybrids of BL cells with a murine teratocarcinoma cell line (*43*).

The expression of sIg in the hybrids between BL cells studied here suggests that strong expression of sIg is uninfluenced by fusion of highly sIg-positive cells with cells having low or undetectable expression of sIg. The Daudi line (as well as its two sublines DUT and DIT) is characterized by very high amounts of surface IgM κ-chain shown to be fully expressed in a Daudi–P3HR-1 hybrid (*17*). This observation would be in line with the autonomous expression of sIg indicated by the amount of and class of light chains expressed on the surface of Raji–Namalwa cell hybrids (*4*). A previously isolated Daudi–Raji hybrid, 8A (*53*), gave only low expression of sIgM (*25*), in marked contrast to the Daudi–Raji hybrid DITRUD-1 described here. A likely explanation for this difference is the different methods by which these hybrids were selected: The first (8A) hybrid was isolated from an adherent HPRT$^-$ Raji derivative and normal Daudi parent cells when hybrids were selected for adherent growth in HAT medium, whereas the second (DITRUD-1) hybrid was selected by standard HAT-medium selection methods from cells in suspension. Since expression of differentiated phenotypes can be related to cell shape (*9*), it is possible that the exceptional result in our previous study (*25*) could be caused by the selection of adherent cells (*53*).

In contrast to the hybrids between BL cells, the hybrid derived by fusion of Daudi and the K562 line showed complete loss of detectable sIg. The Daudi–K562 hybrid showed absence of EBV receptors, as did K562, but showed a very high level of Fc receptors, also similar to K562. Furthermore, in the other BL–BL hybrids, the levels of Fc receptors characteristic of the more highly expressing parent dominated, with the exception of the Daudi–Raji (DITRUD-1) hybrid. The two P3HR-1 sublines (PUT and PICAT) showed absence of EBV receptors in contrast to the parental P3HR-1. Such selection for absence of EBV receptors in cultures of EBV-producing cell lines has been observed previously and is thought to be caused by the selection of cells that are resistant to superinfection by EBV which has been released into the culture medium (*31*). The expression of EBV receptors was fully restored in the two Raji–P3HR-1 hybrids (RUDPUT-2 and RUDPICAT-1), while the P3HR-1–P3HR-1 autohybrid (PICATPO-1) showed the same lack of EBV receptors as the two parents. The expression of C3 receptors in the hybrids paralleled the expression of EBV receptors, and their expression showed a strong correlation (r=0.84).

Rosetting for Ia-like antigens indicated Ia-like expression in all BL lines and their hybrids. The expression was rather low in Daudi, which could be compatible with their continuing differentiation into plasma cells. Ia expression was similar to the high level of Raji in the Daudi–Raji (DITRUD-1) hybrid. As was their K562 parent, both the DUTKO-1 and PUTKO-1 hybrids were negative for Ia, indicating suppression of this B-cell character in these hybrids.

Whereas B-cell markers were suppressed, leukemia and erythroid cell markers were fully expressed in the DUTKO-1 and PUTKO-1 hybrids. Similar to their parental K562 line, both hybrids could be induced for hemoglobin production by treatment with hemin. K562 synthesizes embryonic hemoglobins in response to hemin induction (*49*). The patterns of embryonic hemoglobin production in the hybrids was observed to differ from the parent K562 line: DUTKO-1 produced excess γ- and δ-chains, whereas PUTKO-1 produced excess ε-chains (*54*). It is not now known whether these changes could be due to activation of globin genes contributed by the B-cell genome, similar to the recent example in murine teratocarcinoma–Friend cell hybrids (*55*). Both DUTKO-1 and PUTKO-1 contained high basal and induced levels of heme, as assessed by ^{59}Fe incorporation. K562 expressed high levels of the myeloid–monocytoid lineage-related enzymes β-glucuronidase and lysozyme, which were also expressed in the DUTKO-1 and PUTKO-1 hybrids.

In summary, these findings on DUTKO-1 and PUTKO-1 indicate loss of B-cell markers but retention of the erythroid–leukemia cell markers characteristic of the parental K562. In contrast to these findings, the recently isolated hybrid line between P3HR-1 and the more highly differentiated promyelocytic line HL-60 (*52*) showed the reverse, i.e., retention of B-cell markers but loss of the myeloid markers characteristic of the leukemic parent (*56*). Such findings indicate that the programs of differentiation of BL cells and of leukemia cells are not compatible in the sense that markers of both parents can be coexpressed in hybrid cells, in spite of the suggestion that B-cells and leukemia cells have a common stem cell origin (*12*). That loss of B-cell markers was observed in the hybrids with K562 and the reverse pattern was observed in hybrids with HL-60 could possibly reflect the variable differentiation between the two parent leukemia cell lines.

The present series of hybrids was also used to analyze the patterns of spontaneous and induced EBV antigens, which will be discussed in the following paper (*13*). As in other studies, spontaneous production and inducibility were found to vary in parallel, with the more productive status being dominant in the hybrid. In contrast to the previously studied "allohybrids," the autohybrid of a high and a low virus producer P3HR-1 subline (PICATPO-1) showed a dominant switch-off of the viral cycle. In DUTKO-1, the viral cycle could be induced, in contrast to PUTKO-1 in which it was completely suppressed.

As mentioned, the relatively high chromosomal and phenotypic stability of hybrids like the ones described here between various human hematopoietic cell lines offers the possibility of selection experiments against single phenotypic traits when the fate of additional markers is followed. A particularly interesting property of the K562 line is its high sensitivity to NK cells (*57*), which is exhibited by both PUTKO-1 (*58*) and DUTKO-1 (Masucci G: Unpublished results) as well as by other "primitive" cells such as murine teratocarcinoma cells (*59*). The two hybrids have been selected for NK resistance by in vitro selections, and stable NK-resistant variants have been obtained. This offers the opportunity to correlate the loss of NK sensitivity with other phenotypic markers of these cells.

Human Lymphoma-Lymphoma Hybrids and Lymphoma-Leukemia Hybrids. II. Epstein-Barr Virus Induction Patterns [1,2,3]

George Klein,[4] Jesper Zeuthen,[5] Rosalie Ber,[6] *and* Ingemar Ernberg[4]

ABSTRACT—In addition to the spontaneous expression of markers of the early and late phases of the viral cycle [Epstein-Barr virus (EBV), early viral cycle antigens (EA), and viral capsid antigen (VCA)] by a panel of hybrid cell lines derived by fusion of human hematopoietic cell lines, the induction of these markers by three chemical inducers [5-iodo-2′-deoxyuridine, the tumor promoter 12-*O*-tetradecanoylphorbol 13-acetate (TPA), and sodium butyrate] were analyzed. A variant of the prototype producer of lytic EBV, P3HR-1 (PICAT) was observed to show consistent low spontaneous and induced production of EA and VCA as compared to the P3HR-1 line from which it was derived. An "autohybrid" (PICATPO-1) between these two lines showed a low production of VCA. Hybrids between Raji and P3HR-1 sublines (RUDPICAT-1 and RUDPUT-2) showed reduced expression of EBV antigens. Both hybrids were capable of VCA expression, in contrast to the Raji parent that expressed EA but not VCA. A new Raji-Daudi hybrid (DITRUD-1) expressed spontaneous and induced EA and VCA at levels intermediate between its two parents. A different type of hybrid was derived from a Daudi subline and the K562 leukemia cell line (DUTKO-1) and was found to be capable of spontaneous as well as induced EA and VCA expression. Both DUTKO-1 and DITRUD-1 were similar to Daudi in their induction profile in respect to a very low response to TPA.—JNCI 1982; 68:197–202.

In previous studies on the expression of EBV viral cycle antigens (EA and VCA) in somatic hybrids, we have examined hybrids derived from the fusion of two EBV-positive BL lines (*1–4*) or an EBV-positive and an EBV-negative BL line (*2*), or an EBV-positive BL line and the human leukemia line K562 (*5*). In hybrids between two BL cell lines, EBV-producer status (EA and VCA expression) dominated over nonproducer status, whereas the BL-K562 (P3HR-1-K562=PUTKO-1) hybrid was an absolute nonproducer (*5*). This result is in marked contrast to the expression of EA and VCA in studies when EBV in high multiplicity was transferred by bypassing the membrane barrier into receptor-negative cells of other lineages (*6, 7*). In cells carrying latent EBV genomes, the viral cycle can be induced by a variety of inducers, such as 5-bromo-2′-deoxyuridine (*8*), IdUrd (*9*), sodium butyrate (*10*), the tumor-promoting phorbol ester TPA (*11*), and anti-IgM (*12*).

A similar suppression of virus-producer status as that observed in the P3HR-1-K562 hybrid (*5*) has been previously observed after the hybridization of BL cells with murine or human fibroblasts (*13, 14*). Fusion with epithelial cells led, contrariwise, to more permissive hybrids (*14*). Inducible producer status, mainly studied after IdUrd treatment of hybrid cells, showed essentially similar patterns as spontaneous producer status (*1–5*).

This analysis, based on the interaction of two cell phenotypes in a common hybrid, provides an opportunity to analyze controls that regulate the latency of EBV versus the spontaneous switch on of the viral cycle as well as viral induction by inducing agents. We here examine a series of newly established hybrid lines, described and characterized in the preceding paper (*15*), and morever extend the induction studies to include, in addition to IdUrd, two additional inducers (sodium butyrate and TPA).

MATERIALS AND METHODS

Cell lines.—All lines were maintained in RPMI-1640 medium supplemented with 8% fetal calf serum and antibiotics (100 IU penicillin/ml, 50 μg streptomycin/ml), with additional supplements as described (*15*). The following hybrids and parental cells were used: The hybrid PICATPO-1 was derived from fusion of a CAP^r and TG^r variant of P3HR-1 (PICAT) with a P3HR-1 cell line lacking selective markers (PO). The hybrids RUDPUT-2 and RUDPICAT-1 were derived by fusion of Raji TK^- (RUD) with the $ouab^r$ and TG^r variant of P3HR-1 (PUT) and with the CAP^r and TG^r PICAT variant derived from P3HR-1, respectively. The hybrid DITRUD-1 was derived from fusion of TG^r Daudi (DIT) with Raji TK^- (RUD). The hybrid DUTKO-1 was derived from a $ouab^r$ and TG^r Daudi (DUT) and K562 (KO). Further details are given in (*15*).

Immunofluorescence.—EBV antigen tests were performed on

ABBREVIATIONS USED: BL=Burkitt's lymphoma; CAP^r=chloramphenicol-resistant; EA=early antigens; EBNA=Epstein-Barr virus-associated nuclear antigen; EBV=Epstein-Barr virus; IdUrd=5-iodo-2′-deoxyuridine; $ouab^r$=ouabain-resistant; TG^r=thioguanine-resistant; TK^-=thymidine kinase-negative; TPA=12-*O*-tetradecanoylphorbol 13-acetate; VCA=viral capsid antigens.

acetone-fixed smears. The EBV-determined nuclear antigen EBNA was stained by anticomplement immunofluorescence (*16*). We identified EA-positive cells by direct fluorescence (*17*) using the F_1 Esther conjugate at a 1:40 dilution. We stained VCA-positive cells by indirect fluorescence (*18*) using anti-VCA-positive, anti-EA-negative serum from a healthy donor (MBF) at a dilution of 1:10, followed by an anti-Fc (*8*) conjugate (Hyland Laboratories, Los Angeles, Calif.) at a dilution of 1:20.

EBV induction experiments.—The hybrids and parental cells were exposed to 25 μg IdUrd/ml (*9*), 3 mg sodium butyrate/ml (*10*), or 10 ng TPA/ml (*11*) and harvested after 3, 6, or 6 days, respectively. The frequency of EA- and VCA-positive cells was estimated by counting 1,000 cells in each smear. Four or five tests were performed with each cell-inducer combination.

RESULTS

PICATPO-1 (P3HR-1–P3HR-1 "Autohybrid")

The P3HR-1 line is often regarded as a prototype EBV-producer line. P3HR-1 virus has lost its transforming ability but is capable of lytic infection. The other prototype EBV producer, B95-8, produces a transforming virus incapable of lytic infection. Unlike B95-8, P3HR-1 cells have the tendency to "switch off" the viral cycle on prolonged propagation, which reduces the expression of surface receptors for EBV (*19*). These changes probably reflect strong internal selection in culture for reduced EBV production as well as reduced adsorption-infection by lytic, superinfecting virus.

The CAP^r and TG^r PICAT variant of P3HR-1 showed a consistently lower spontaneous expression of EA and VCA than did the P3HR-1 line from which it was derived by several cycles of selection (text-fig. 1). The same difference was found for induced expression, for the P3HR-1 line was considerably more inducible, in particular by TPA, than was the variant PICAT line. The autohybrid PICATPO-1 formed by fusion of these two lines was less inducible than either of its parents, and its spontaneous producer status resembled that of the low-producer PICAT; however, TPA inducibility was similar for PICAT and the PICATPO-1 hybrid. The dominance of the low-producer, low-inducibility status in PICATPO-1 suggested that the control mechanisms responsible for the emergence of the low-producer variants might be of a negative, trans-acting nature.

A variable proportion of EA-positive cells proceeded to VCA synthesis. This was expected since P3HR-1 cells did not have an internal block to VCA production.

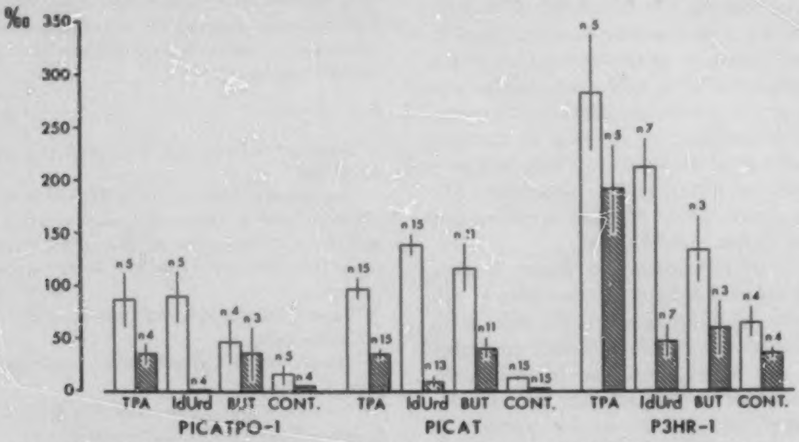
RUDPICAT-1 and RUDPUT-2 (Raji–P3HR-1 Hybrids)

The Raji line is the prototype "abortive producer" cell line; i.e., EA can be induced but the viral cycle does not proceed further to viral DNA replication and VCA synthesis (*1–3, 9*). As expected, the Raji TK^- (RUD) parent was noninducible for EA expression by IdUrd in contrast to the other two inducers TPA and sodium butyrate, which induced EA at a low level (text-fig. 2). Compared to the P3HR-1-derived PICAT and PUT parental cells, both the RUDPICAT-1 and RUDPUT-2 hybrids showed a reduced inducibility but to different extents. The inducibility of the RUDPICAT-1 line was not strongly reduced compared to the highly inducible PICAT parent, whereas the inducibility of RUDPUT-2 was almost as low as that of the slightly inducible Raji TK^- (RUD) line.

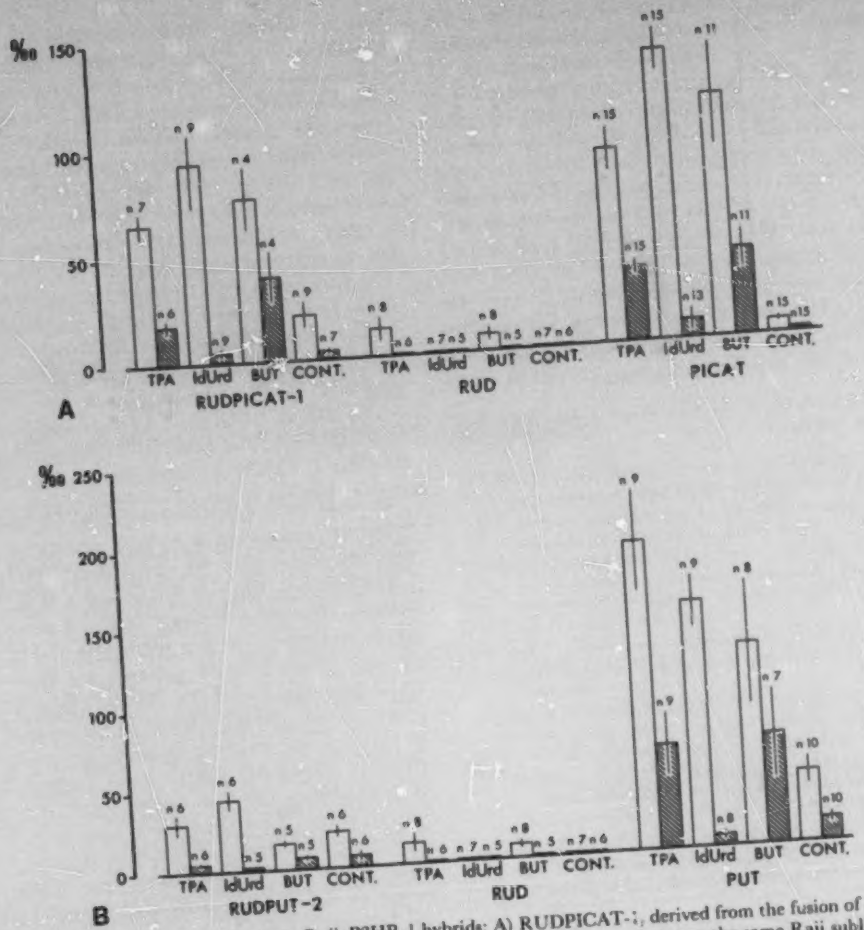
The block between EA and VCA expression in Raji cells was lifted in both hybrids. The "recessiveness" of this barrier is interesting: It leads support to the idea that Raji was defective with respect to either EBV-DNA or cellular factors necessary for viral DNA replication and/or production of VCA. Note that the RUDPUT-2 hybrid also could produce VCA, in spite of its low Raji-like EA inducibility.

DITRUD-1 (Raji–Daudi Hybrid)

In contrast to Raji, the Daudi line was a producer line capable of EA and VCA expression (text-fig. 3). The Daudi parent showed a relatively low response to TPA, in contrast to its good inducibility with either IdUrd or sodium buty-



TEXT-FIGURE 1.—Induction of EA (*open columns*) and VCA (*shaded columns*) in PICATPO-1, an autohybrid from two parental P3HR-1 sublines—PICAT and P3HR-1, respectively. Untreated control (CONT.) cells and cells induced by TPA, IdUrd, and sodium butyrate (BUT) are compared. Staples indicate the range for SE; *n*=No. of tests performed.



TEXT-FIGURE 2.—Inducibility and producer status of two Raji–P3HR-1 hybrids: A) RUDPICAT-1, derived from the fusion of a TK⁻ Raji subline (RUD) and a CAP^r and TG^r subline (PICAT) of P3HR-1, and B) RUDPUT-2, derived from the cross between the same Raji subline and the ouab^r and TG^r subline of P3HR-1 (PUT). Symbols and abbreviations are as in text-fig. 1.

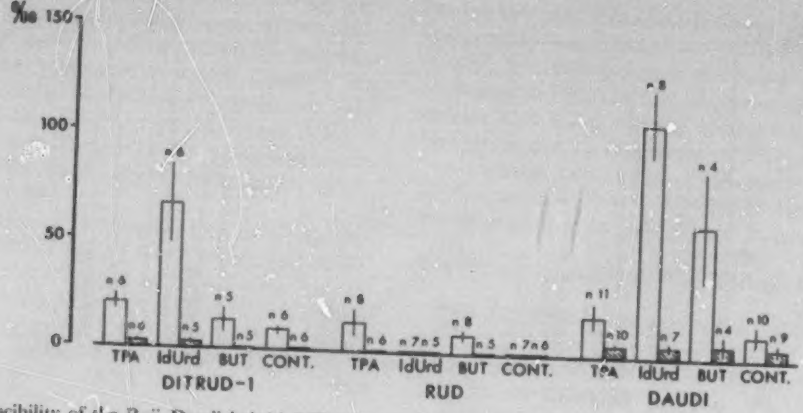
rate. This considerable difference between the effects of the three chemical inducers was unique among many EBV-positive cell lines that were tested for their inducibility with IdUrd, TPA, and sodium butyrate (results not shown).

The low inducibility by TPA was not compensated in the DITRUD-1 hybrid, which behaved similarly to the Daudi parent. With IdUrd, DITRUD-1 was inducible at an intermediate level between its two parents. The response to sodium butyrate was a further example of the different activities of the three inducers: It was high in Daudi but low (at a level similar to Raji) in the DITRUD-1 hybrid. VCA expression was low in the DITRUD-1 hybrid, but it did occur at a low level similar to that of Daudi in cultures treated with TPA or IdUrd.

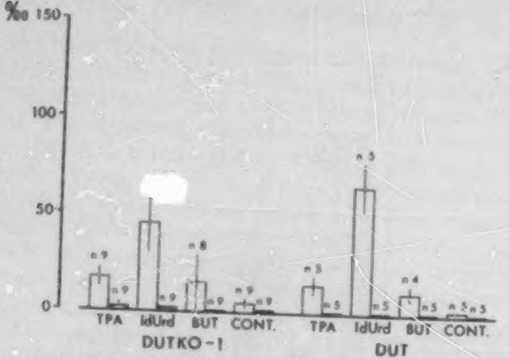
The relatively high level of expression of viral cycle antigens in the DITRUD-1 hybrid was somewhat different from our previous results for another Raji–Daudi hybrid, 8A (*2*), which was selected for an adherent phenotype. In 8A, spontaneous and IdUrd-induced EA production was low, corresponding to the level of its Raji parent. This difference corresponded to the observation of a more Daudi-like phenotype of DITRUD-1, even in regard to surface marker expression (*15*).

DUTKO-1 (Daudi–K562 Hybrid)

The ouab^r and TG^r subline of Daudi (DUT) expressed somewhat less EA and VCA spontaneously as well as when induced, as compared to its parent Daudi line (text-fig. 4). The EBV-negative K562 line was negative in all EBV antigen tests, as expected (results not shown). Similar to the normal Daudi line, the DUT line was highly inducible by IdUrd but not by TPA; however, DUT responded much less to sodium butyrate than did the normal Daudi line. Another difference was that DUT was virtually negative for VCA inducibility and spontaneous EA production when compared to those of the normal Daudi line. The DUTKO-1 hybrid was clearly inducible by all three inducers and also showed spontaneous expression of viral cycle antigens. The induced levels were comparable or slightly lower than those for the DUT parent. This result is in marked contrast to a previously examined hybrid between K562 and P3HR-1



TEXT-FIGURE 3.—EBV inducibility of the Raji-Daudi hybrid DITRUD-1, as compared with the RUD and the Daudi (TG^{r}) parents. Symbols and abbreviations are as in text-fig. 1.



TEXT-FIGURE 4.—Inducibility of the Daudi-K562 hybrid DUTKO-1, as compared with the ouab^{r} and TG^{r} Daudi subline parent DUT. K562 is an EBV-negative line. Symbols and abbreviations are as in text-fig. 1.

(PUTKO-1) in which a totally eclipsed expression of viral cycle antigens was observed with all of the three inducing agents discussed here (*5*). The two hybrids, however, carry different numbers of EBV genomes: PUTKO-1 carries about 22; DUTKO-1, about 84 (*20*).

DISCUSSION

Somatic hybrids derived from the fusion of EBV-positive human lymphoma lines with each other or with cell lines of other derivations are useful for defining some of the control mechanisms involved in the maintenance of EBV latency. In our previous studies, the hybrid formed by fusion of two B-cell-derived lines usually expressed the more permissive parental condition, i.e., spontaneous production and inducibility of the respective parent; whereas B-cell lines fused with cells of certain other lineages, such as the erythroleukemia line K562 or with fibroblasts, produced hybrids with more or less completely eclipsed inducibility and producer status (*1–5, 13*).

In the present study, these conclusions were re-examined on a newly established series of hybrids described in the preceding paper (*15*). In addition to the previously tested inducer IdUrd, we have tested two other inducers: the tumor-promoting agent TPA and sodium butyrate.

Several new conclusions could be drawn. For the first time, we examined a hybrid produced by fusion of two sublines of the same BL cell line (P3HR-1) (the PICATPO-1 autohybrid). One of the sublines (PICAT), a CAP^{r}, TG^{r} variant, showed a strongly reduced productivity–inducibility as compared to the wild-type P3HR-1 line, its fusion partner. Nonproducer variants are known to arise during serial propagation of the P3HR-1 line. The fact that serial propagation regularly leads to the loss of virus production in this cell line suggests that the nonproducing cells have a selective advantage. Our results suggest that the switch-off of inducibility may be under negative, perhaps repressor-type control. This conclusion contrasts with our previous studies on the fusion of two (producer vs. nonproducer) BL lines when the opposite was seen. Clearly, the producer versus nonproducer status of different hybrids depends on the interaction of the stably established regulatory mechanisms confronted with each other in a given hybrid.

This point is further illustrated when the two independently derived Raji-P3HR-1 hybrids RUDPICAT-1 and RUDPUT-2 are compared. They were derived from the fusion of the same two BL lines, although different variant sublines with different phenotypes of P3HR-1 were used. The inducibility patterns of the two hybrids were quite different. These results indicate that even sublines of cells might differ markedly with respect to such regulatory mechanisms.

An additional point is illustrated when the DITRUD-1 hybrid in the present study was compared with an additional independently derived Daudi-Raji hybrid, 8A (*2*). While phenotypic characteristics of Raji dominated in 8A with regard to both surface immunoglobulin and EBV inducibility, DITRUD-1 resembled Daudi with regard to both properties.

The dominance of the characteristics of one parent with regard to surface and other phenotypic markers does not fully explain the inducibility patterns, however. This is made particularly clear by the Daudi-K562 (DUTKO-1) hybrid of the present study. We previously examined a P3HR-1-K562 hybrid, PUTKO-1 (*5*), in which the K562 phenotype dominated with respect to each parameter studied. B-cell markers were suppressed while the characteristic erythroid differentiation, high natural killer sensitivity, and surface receptors of K562 were expressed (*5*). DUTKO-1 has a very similar phenotype to that of PUTKO-1, as shown in the preceding paper (*15*). Both hybrids are 100% EBNA-positive and have multiple EBV genomes. However, PUTKO-1 is completely noninducible by all three agents studied, whereas DUTKO-1 is inducible by all. The two hybrids, however, differ in their average EBV genome copy number: PUTKO-1 carries 22 EBV genome equivalents while DUTKO-1 has 84 (*20*). In spite of the fact that IdUrd fails to induce viral antigen synthesis in PUTKO-1 cells (*5*), viral transcription has been shown to increase from 10 to 25% after IdUrd induction (*20*). In DUTKO-1 cells, IdUrd induced viral transcription from more than 40% of the EBV DNA, whereas TPA had no significant effect. RNA extracted from the polyribosomes of PUTKO-1 or DUTKO-1 cells contained only about 20% of the viral RNA sequences found in whole-cell extracts, whereas for P3HR-1 cells all the viral RNA transcripts could be found in polyribosomes (*20*).

These findings suggest the presence of additional translation control mechanisms that permit only certain viral RNA sequences to be associated with polyribosomes that might contribute to regulation of the expression of EBV antigens in the two BL-K562 hybrids. This suggests that two opposing forces are at work. The K562 genome tends to suppress all B-cell-associated characteristics, including the ability to produce EBV antigens. This control can be overridden, however, if a sufficient number of viral genomes is present. Since the ability to keep the viral cycle appears to be a B-cell-dependent characteristic, it is conceivable that the virus utilizes some differentiated phenotypic property of the B-cell to assure its latency, probably in a repressor-like fashion. If this control is of limited power, it will be overridden by an excessive number of viral genomes.

So far in this discussion, "induction" was used to mean the "point of no return," as signaled by the appearance of EA. In certain cells (prototype: Raji) the EBV cycle is hampered by a second carrier—between EA and replicative viral DNA (positive in subsequent VCA) synthesis. In the present study, this barrier was absent in both Raji-P3HR-1 hybrids and in the Daudi-Raji hybrid. This agrees with our previous findings and suggests that the Raji cell may be deficient in some component required for entry into the late part of the cycle.

This defect could be either viral or cellular. Since both Raji parents in the present series of hybrids carry endogenous EBV genomes, the present results only allow the conclusion that whatever the defect in Raji, it does not seem to be caused by negative, trans-acting factors that affect the expression of the viral genome. Further studies (results not shown) on a previously derived hybrid between Raji and the EBV-negative lymphoma line BJAB (*2*), have clearly indicated that, while EA production is even amplified in this hybrid after treatment with any of the three inducers used here, there is absolutely no production of VCA; i.e., the block between EA and VCA production is not lifted, suggesting that the abortive producer phenotype of Raji is caused by a deficient viral genome and not by a defective cellular mechanism. Recent analyses of the structure of Raji EBV DNA have shown that the Raji EBV genome is indeed defective since it contains two deleted sequences (Bornkamm G: Personal communication).

The three inducing agents (TPA, IdUrd, and sodium butyrate) acted largely in parallel but with some notable exceptions. The Daudi line did not respond well to TPA in contrast to its good inducibility with IdUrd and sodium butyrate. This difference was also observed in the hybrids of Daudi with other lines (DITRUD-1, DUTKO-1). In the Daudi-Raji (DITRUD-1) hybrid, there was also a dissociation between the IdUrd and sodium butyrate induction patterns. This phenomenon suggests that while the three agents may act similarly in most cells, the agents do not show the same activity with all cells, perhaps due to differences in the entry or processing of the drugs.

Ganglioside Patterns: New Biochemical Markers for Human Hematopoietic Cell Lines[1]

Günter Rosenfelder,[2] Andreas Ziegler,[3] Peter Wernet,[3] *and* Dietmar G. Braun[2,4]

ABSTRACT—The ganglioside patterns from a representative collection of 20 human B-cell, T-cell, null cell, myeloid cell, and early erythroid cell lines were determined. Radioactive sugar-labeled gangliosides from cultured cells were extracted, analyzed, and quantitated by high-performance thin-layer chromatography (HPTLC) and high-pressure liquid chromatography, essentially according to the polarity of the oligosaccharide chain. The ganglioside labeling patterns of the human cell lines were in some cases extremely complex, since more than 100 components could be separated upon two-dimensional HPTLC, e.g., in the case of a promyelocytic cell line. Each type of cell showed a characteristic pattern: Null cell lines were much less complex than T-cell lines, and myeloid and erythroid lines exhibited characteristic patterns as well. Although clearly distinguishable from all other cell lines, the B-cell lines showed a high degree of heterogeneity. Therefore, gangliosides can be expected to serve as additional markers to establish the origin of a cell line or to classify pathologic cell populations.—JNCI 1982; 68:203–209.

Considerable effort has been devoted to the serologic, biochemical, genetic, and functional characterization of human hematopoietic cell lines, since several of these are believed to be the in vitro correlates of cell types responsible for a variety of hematologic disorders. Analyses of chromosomal abnormalities (*1, 2*), morphologic and cytochemical characteristics (*3*), surface glycoprotein patterns (*4–8*), serologic markers (*9–12*), and functional attributes (*12–14*) have already established some differences among these cell lines. The recent finding that GSL are highly characteristic moieties of murine lymphoblastoid tumor cell lines (*15*) prompted us to perform similar analyses on a representative panel of human hematopoietic cell lines for the identification of new differentiation markers. The chromatographic analysis of radioactively labeled gangliosides from these lines revealed patterns that appear suitable for classification purposes.

MATERIALS AND METHODS

Cell lines.—The human cell lines used and some selected markers are given in table 1. ERL proliferated from a cultured paraaortic lymph node of a patient with testicular teratocarcinoma; it was supplied by Dr. R. Löwer and Dr. R. Kurth of the Medical University Clinic. BRW was obtained from Dr. I. Doxiadis, University of Munich, Munich, F.R.G., and was originally derived from a patient with an unclassified leukemia. SH00 and SH02 lines were established by EBV transformation of lymphocytes from umbilical cord blood (Schulte-Holthausen H: Unpublished results) and were obtained from Dr. Kurth. The K562 cell line was established from a patient with chronic myeloid leukemia in terminal blastic crisis (*16*), and it has characteristics of early erythroid cells (*17*). The origin and some properties of the following lines have already been described (*18*): KR3598, Priess (*19*), and Bri-8 (*20*) are EBV-transformed normal B-cells, while DAUDI (*21*), Raji (*22*), NC37 (*23*), BJAB (*24*), and EB3 (*25*) are derived from patients with Burkitt's lymphoma. MOLT-4 (*26*), JM1 (*27*), CCRF-CEM (*28*), and CCRF-HSB-2 (*29*) are cell lines derived from patients with acute lymphoblastic leukemia of the T-cell type; KM3 (*29*) and Reh (*30*) have been classified as null lymphoid cells because they lack the classical markers of B-cells and T-cells. Finally, the cell line HL-60 (*31*) bears characteristics of promyelocytes.

With the exception of JM1, all cell lines were grown in Dulbecco's modification of Eagle's minimum essential medium (Boehringer, Mannheim, F.R.G.) supplemented with 10% fetal calf serum (Seromed, Munich, F.R.G.), 2 m*M* glutamine, 200 U penicillin/ml, and 200 µg streptomycin/ml. JM1 was cultured in RPMI-1640 medium containing 25 m*M* HEPES[5] buffer (Gibco-Biocult, Glasgow, Scotland); the other ingredients were prepared as above.

Radioactive incorporations and isolation of gangliosides.[6]—Cells were radioactively labeled in 50 ml growth medium supplemented with 0.5 µCi D-[1-^{14}C]galactose/ml (sp act 60 mCi/mmol) and 0.5 µCi D-[1-^{14}C]glucosamine hydrochloride/ml (sp act, 57.8 mCi/mmol) (both from Amersham-Buchler, Braunschweig, F.R.G.). Cells were seeded at a concentration

[5] 4-(2-Hydroxyethyl)-1-piperazine ethanesulfonic acid.

[6] Abbreviations of gangliosides G_{M1}, G_{M2}, G_{M3}, and G_{D1a} are according to the nomenclature given in the *Recommendations of the Commission on Biochemical Nomenclature IUPAC-IUB* (1976). G=ganglioside, M=monosialo, and D=disialo. *Arabic numbers* indicate sequence of migration in thin-layer chromatograms.

of 2.5×10^5/ml or 5×10^5/ml. In most cases, incorporations were terminated after 48 hours, but cell lines Reh, KM3, JM1, and KR3598 were grown for longer periods up to 116 hours (KM3). About 5×10^7 cells were finally harvested by centrifugation, washed twice with phosphate-buffered saline (pH 7.3), and repeatedly extracted with chloroform:methanol (2:1 and 1:1, vol/vol). The ganglioside fraction was separated from the other lipids by a modified Folch partition and subsequent DEAE-Sepharose chromatography of the dialyzed upper phases (*15, 32*).

Chromatographic analysis of gangliosides.—An aliquot of the ganglioside fraction (10^4 cpm) obtained from the cell lines was analyzed on the basis of polarity on Merck silica gel HPTLC plates. Plates were developed in a solvent system of chloroform:methanol:water (55:45:10, vol/vol/vol, containing 1 m*M* $CaCl_2$). For two-dimensional HPTLC analyses, plates were developed for the first dimension as above, then dried and chromatographed for the second dimension with the use of chloroform:methanol:2.5 *M* NH_4OH (60:35:8, vol/vol/vol, containing 1 m*M* $CaCl_2$). Dried chromatograms were autoradiographed on Kodak RP Royal X-Omat X-ray films for 6 days. For comparison, CBA/J mouse brain gangliosides were applied as cold standards and subsequently stained with resorcinol (*33*).

HPLC analyses of the ganglioside fractions ($2-3\times10^4$ cpm) were performed on two Zorbax Sil columns in series (250×4.6 mm; E. I. du Pont de Nemours, Wilmington, Del.) with the use of two Altex model 110 pumps (Altex Scientific Inc., Berkeley, Calif.), a model 7120 injector with a 20-μl sample loop (Rheodyne, Berkeley, Calif.), a model LB 503 radioactivity flow-through monitor (Berthold Laboratories, Wildbad, F.R.G.) with a 200-μl flow cell containing glass scintillator beads, and a four-channel model 314 recorder (W+W Electronics, Basel, Switzerland). One pump provided a constant flow (0.45 ml/min) of chloroform:methanol:water:formic acid (60:35:4:1, vol/vol/vol/vol) through the columns, whereas the second pump provided a constant flow (0.05 ml/min) of the alkaline detergent Extran (E. Merck A.G., Darmstadt, F.R.G.) in water (5% vol/vol) into the main stream from the columns to the radioactivity monitor. The addition of Extran avoided memory effects caused by nonspecific absorption of gangliosides to glass by permanently "rinsing" the glass scintillator beads. Although in-line detection proved indispensable for optimization of separation conditions, accurate quantitation by means of the radioactivity monitor proved to be problematic due to high background signal noise and solvent quenching. Hence 1-ml fractions were collected, the organic solvent was evaporated under a gentle stream of air, and the radioactivity was counted in an Aquasol scintillator with the use of an Intertechnique liquid scintillation counter (model SL 4000; Nucletron SA, Lausanne, Switzerland).

RESULTS

The incorporation of ^{14}C-labeled sugars as label into dividing leukocytes has greatly facilitated the qualitative and quantitative analyses of GSL (*15, 34, 35*). Although incorporation of [^{14}C]galactose and [^{14}C]glucosamine into the ganglioside fraction varied considerably from cell line to cell line in this study, radioactivity of this fraction generally accounted for about 90% of that incorporated into total GSL (table 1).

Isolated gangliosides were analyzed either by HPTLC or,

for the quantitation of radioactive bands, by HPLC. HPLC proved less laborious and more reliable than the one used previously (*15*), where zones of radioactivity had been scraped off the silica plates before counting. Patterns of gangliosides from 12 selected lines and quantitation of the predominant bands from these lines are depicted in figures 1 and 2. A characteristic of all human as opposed to murine T-cell and B-cell lines tested was the presence of a double band in the ganglioside G_{M3} range. Furthermore, a distinct difference between lymphoid and other human hematopoietic cell lines became apparent: In B-cells, T-cells, and null cells, this double band (with the exception of triple bands in the G_{M3} range in KR3598 cells described below) contained between 52 and 85% of the radioactivity present in all gangliosides; this finding contrasted with the findings with the promyelocytic line HL-60 and the erythroid precursor line K562, in which these two components account for only 30–40% of the total cpm of the ganglioside fraction.

The ganglioside fraction of B-cell lines showed considerable heterogeneity (fig. 1). The patterns with the least complexity were those of Priess and ERL, two lines with totally different origins. The umbilical cord blood lines SH00 and SH02 (not shown) yielded the simplest patterns, consisting of virtually only the double band in the G_{M3} range. KR3598 was distinguishable from all other cell lines by a strong band (accounting for 20% of the total radioactivity) with a slightly higher retardation factor value than that of the double band in the G_{M3} range. The banding patterns of Bri-8 and BRW were quite similar in spite of clear-cut quantitative differences. Again, the origin of these lines was entirely distinct. The most pronounced difference among the B-cell lines was found when the Burkitt's lymphoma line DAUDI was compared with all other B-cell lines. The other Burkitt's lymphoma lines Raji, NC37 [apparently a subline of Raji (*23*)], BJAB, and EB3 (patterns not shown) resembled DAUDI.

GSL patterns were established for four T-cell lines: MOLT-4, JM1 (fig. 2), CCRF-CEM, and CCRF-HSB-2 (not shown). Despite quantitative differences, the banding patterns were more similar to each other than were the patterns of any of the other cell lines tested. In particular, a strongly labeled doublet in the G_{D1a} position appeared to be a characteristic of the T-cell lines (fig. 2).

Easily distinguishable from all other lines by their gangliosides, the non-T-cell, non-B-cell lines Reh and KM3 each exhibited two distinct bands in the G_{M2} range of about equal intensity. In addition to null cells, both bands appeared to be present only in the promyelocytic cell line HL-60 as part of an extremely complex pattern, which was, irrespective of several overlaps, entirely different from that of all other lines examined (fig. 2).

Finally, the erythroid precursor cell line K562 also exhibited a complex ganglioside pattern with a large number of bands. Although distinct from all other cell lines tested, there appeared to be a definite relationship with T-cell lines, whose bands in the G_{1Da} range were also present in K562; the same held true for bands in the G_{M2} region. The only clear-cut qualitative difference appeared to be a doublet in the G_{M2} range: Both T-cell lines possessed only one band at the retardation factor position of the K562 doublet. The slower migrating component of this doublet may have been identical with the faster moving band from the G_{M2} range of Reh and KM3.

The possibility that ganglioside patterns could be even more complex than suggested by the results presented above was examined by two-dimensional HPTLC. The cell lines MOLT-4, Bri-8, KM3, and HL-60 may serve as examples (fig. 3). Under these conditions even the restricted null cell pattern of KM3 consisted of an amazing number of spots. Two-dimensional HPTLC resolved single bands into two to three and sometimes more components. The two-dimensional chromatograms of cell lines with complex GSL patterns already after one-dimensional chromatography (such as MOLT-4 or HL-60) are good examples of the resolving power of this method.

DISCUSSION

Conventional procedures of cell classification were of considerable benefit when serologically defined surface and cytoplasmic markers became available. However, the cALL antigen for acute lymphoblastic leukemia cells has recently been found on a variety of B-cell and T-cell lines (*36, 37*). Hence there is a clear-cut need for additional markers identifying the origin of normal cells and of pathologic (e.g., leukemia and lymphoma) cell populations by other than established markers. GSL have proved to be valuable markers for certain murine cell lines (*15*); their analysis was therefore extended to human hematopoietic cells with the hope of establishing an alternative system of differentiation markers.

The ganglioside patterns depicted in figures 1 and 2 appear to be unrelated to the human cell surface antigens listed in table 1. This may not be too surprising because all these antigens are proteins, although, possibly, a particular GSL in the cell membrane could be a consequence of the non-expression of other antigens. Probably the most interesting aspect of the results given in this article is the possibility of defining ganglioside patterns characteristic of particular types of human cells. The most obvious case is that of the non-T-cell, non-B-cell lines KM3 and Reh, whose banding patterns, though virtually indistinguishable, are entirely distinct from those of all other cell lines investigated.

The B-cell lines analyzed exhibited a remarkable degree of heterogeneity in their GSL patterns. It is unlikely that the complex patterns of DAUDI and of the other cell lines derived from Burkitt's lymphoma are due to the absence of HLA-A, HLA-B, and HLA-C antigens, since the GSL patterns from the other Burkitt's lymphoma lines expressing these antigens were closely similar to those from DAUDI. The in vitro EBV-transformed lines and B-cell lines of other origins gave relatively simple GSL patterns, the most simple being those of unbilical cord blood lines. It thus appears that an analysis of gangliosides could lead to a subdivision of B-cell lines into Burkitt's lymphoma-derived lines and cells from other origins. An analysis with the use of monoclonal antibodies (Ziegler A: Submitted for publication) supports this conclusion.

The T-cell GSL patterns established here are considerably more complex than the B-cell GSL patterns (with the exception of DAUDI), and they bear remarkably little resemblance to the patterns of the B-cell lines. Several bands appear to be shared among T-cells, the promyelocytic cell line HL-60, and the chronic myeloid leukemia-derived cell line K562. This finding may indicate a closer relationship between myeloid cells and T-lymphocytes than was previously postulated. Although it cannot be decided on the basis of these data whether the divergence between T-cells and B-cells occurs earlier in hematopoiesis than that between T-lymphocytes and myeloid cells, the frequent occurrence of leukemia cells bearing characteristics of both myeloid and T-cells (*38*, *39*) points to the same direction, i.e., that myeloid cells and T-cells are closely related.

The reasons for the complexity of ganglioside patterns exhibited by human hematopoietic cell lines are unknown. The many GSL spots seen after two-dimensional chromatography in cell lines arrested at different stages of hematopoiesis must be a consequence of regulatory events during differentiation, since the GSL content of cell surfaces depends on the activity of sugar- and acyl-transferases, hydrolases, and various other enzyme systems. On what level these regulatory control mechanisms are exerted, (transcriptional, translational, or post-translational) cannot be decided at this stage, but there are a number of ways to approach these questions [*see*, e.g., (*40*)]. Although it appears to be unsuitable for routine work in its present form, the establishment of ganglioside patterns may be complementary in all those cases in which conventional analytic approaches have failed to indicate the origin of a cell line or a pathologic cell population, as in the case of the Sternberg-Reed cell (*2*).

Risk Factors for Breast Cancer in Women in Northern Alberta, Canada, as Related to Age at Diagnosis[1,2]

Jay H. Lubin,[3] Patricia E. Burns,[4] William J. Blot,[3] Alan W. Lees,[4] Carol May,[4] Linda E. Morris,[3] *and* Joseph F. Fraumeni, Jr.[3,5]

ABSTRACT—A population-based case–control study involving interviews with 577 female breast cancer patients and 826 controls in northern Alberta, Canada, revealed that some determinants of breast cancer varied according to age. Among women under age 45, risk factors included a younger age at menarche, late age at last birth, high parity, and recent use of oral contraceptives. At older ages risk was related to natural as opposed to surgical menopause, late age at first birth, low parity, late age at natural menopause, and tonsillectomy. At all ages there was an increased risk of breast cancer associated with difficulty in conceiving, benign breast disease, not having breast fed, and a history of breast cancer among mothers or sisters. For some variables the age differences were pronounced; the combination of low parity and late age at first birth was associated with a sevenfold increase in breast cancer risk at ages 55–80 but a slight decrease at ages under 45. The effect of tonsillectomy steadily increased with age and represents a new lead, but certain features of the data suggest that the link to oral contraceptives among younger women and the inverse relation to breast feeding at all ages may not be causal. Even though design limitations (cases interviewed in a different setting from controls) appeared not to influence conclusions, the results may have been subjected to interview bias and thus should be interpreted cautiously.—JNCI 1982; 68:211–217.

The causes of breast cancer among postmenopausal women may differ from those among premenopausal women (*1–6*). Taking advantage of a comprehensive reporting system in northern Alberta, Canada, in which virtually all women with breast cancer diagnosed during 1976–77 were identified and interviewed, we conducted a case–control study to evaluate differences in risk factors according to age at diagnosis.

MATERIALS AND METHODS

Breast cancer cases were drawn from the breast cancer registry (*7*) operated in conjunction with the Alberta Cancer Registry (*8*). The case group consisted of 631 women with breast cancer reported in northern Alberta during the 2-year period 1976–77. These women constitute all cases, since cancer registration is mandatory. Upon referral to diagnostic breast clinics held at the Cross Cancer Institute, 565 breast cancer patients were interviewed by two trained nurses, using a questionnaire designed to obtain information on descriptive variables and potential risk factors for breast cancer.

An age-stratified random sample, selected from social insurance files covering the entire population, of 1,268 women living in northern Alberta as of May 1978 was identified to act as a control group. The files of these women were checked against the cancer registry files to eliminate and replace those registered with breast cancer. Because of the small number of young patients with breast cancer, a greater percentage of young controls was selected to increase the power of detecting risk factors associated with early onset of disease. The resultant powers to detect a fixed level of risk were similar within our defined age categories. The same questions asked by the nurses interviewing cases, some modified slightly to adjust for a different interview setting, were asked of the controls in their homes by trained interviewers during the fall of 1978. Nearly all questions required an answer in closed form (e.g., yes or no or a response in one of but a few categories). Of the control women, 352 were not interviewed because of refusal to participate (109), incompetence (13), death (4), language difficulty (26), departure from the survey area (71), inability to locate (78), unavailability (36), and other reasons (15). Nine were interviewed but later excluded because of a previously diagnosed breast cancer. Thus a total of 907 apparently breast cancer-free women from the general population was available for comparison.

The analyses were restricted to the 577 cases and 826 controls aged 30–80 and were aimed at the examination of risk factors according to age at diagnosis for cases or age in January 1977 for controls. Age groups were selected as 30–44, 45–54, 55–64, and 65–80 years. Estimates of RR were calculated for various factors within each age stratum. The method of Gart (*9*) was used to estimate summary RR over age, when appropriate, or other strata and to obtain CI. Tests for linear trends for variables with multiple exposure

---

ABBREVIATIONS USED: CI=confidence intervals; OC=oral contraceptive(s); RR=relative risk(s).

categories were done with the use of the Mantel extension procedure (*10*). The number of cases and controls used in the analyses of different factors varied slightly as a result of incomplete information on some variables.

To examine simultaneously several risk factors and to test interactions with age at diagnosis, we analyzed the data by using a binary logistic model for disease incidence (*11–13*). For these analyses only the 386 cases and 585 controls with data values for all variables considered were used. Although a rather large proportion of subjects was excluded (34% of cases and 29% of controls), results from the logistic analyses closely paralleled those from the crude and stratified analyses. A core set of variables related to disease status was defined and included in all models so as to adjust for potential confounding. This core set included variables for the four age strata, an additional linear age variable within the strata, religion (one variable indicating if Protestant and one if Catholic), and the occurrence (yes or no) of a previous biopsy for benign breast disease. When a potential risk factor was considered, the model included the core set, other potentially confounding variables (where appropriate), and the factor of interest. Tests of significance for various factors were done with the use of a likelihood ratio procedure.

RESULTS

General.—Table 1 summarizes some demographic characteristics for cases and controls. Although the sampling procedures specified a larger proportion of young controls, the mean ages of cases and controls were similar within the broad age strata. Most individuals were born in Canada, but for all ages, the proportion was higher for cases, while the proportion of Asian-born individuals was higher for controls. A higher proportion of cases was Protestant, but there were no significant differences according to level of education.

TABLE 1.—*Demographic and education variables for 577 cases and 826 controls*

Table 2 presents the RR of breast cancer, according to age of diagnosis, associated with various risk factors examined in this survey. The number of cases and controls upon which the RR are based are given in table 3.

Age at menarche.—As shown in table 2, late age at menarche was associated with a decreased risk of breast cancer. The protective effect, however, was more pronounced in the youngest age stratum.

Age at first birth and parity.—There were linear trends of increased risk with late age at first birth compared to first birth before age 20 in each of the three oldest age strata. Similarly, increased risks were linked to low parity at older ages. At ages 30–44, however, the pattern in risk with low parity was reversed, while no significant effect with age at first birth was seen.

Table 4 shows that there were separate effects of both variables at the older ages. Among older women there was some evidence of interaction between the two variables, as the effect of low parity tended to be more pronounced among those with early age at first birth. [RR estimates for high (>3) and low (1–3) parity, if we summarize over the three oldest age groups, were, respectively, 1.0 and 2.8 (1.1, 7.0), 2.6 (1.4, 4.9) and 3.6 (1.9, 6.7), and 4.5 (2.2, 9.3) and 5.1 (2.8, 9.3) among women with a first birth at ages <20, 20–24, and ≥25, respectively, with an estimate of 6.1 (3.1, 11.6) for nulliparous women. All estimates were computed relative to women of high parity and early age (<20) at first birth]. At ages 30–44, after adjustment for parity, there was little or no trend with age at first birth. There remained, however, a significantly increased risk associated with high, rather than low, parity [RR=1.8 with 95% CI (1.1, 3.1) for women with parity >3 compared to those with parity ≤3 after adjustment for age at first birth].

Considering only parous women, we used a logistic model to analyze simultaneously age at first birth and parity and the interactions of these variables with each other and with age at diagnosis, while we controlled for the core set, use of OC and age at menarche. For the interaction effects, age at first birth and age were dichotomized (≥20 vs. <20 and ≥45 vs. <45, respectively). The risk associated with age at first birth significantly varied by age (with the effect limited to older ages) ($P=0.02$) but did not vary by parity category ($P=0.71$). Although much of the overall influence of parity was accounted for by age at first birth, the logistic analysis showed an interaction of this variable with age ($P=0.03$), even after we adjusted for the interaction between age at first birth and age ($P=0.12$).

Age at last birth.—For parous women, there was a slightly increased risk associated with an older age (≥35) at last birth within each age stratum and a linear trend at ages 30–44 (table 2). The previously described excess risk associated with high (<3) parity in the youngest age group was strongest among women whose last birth occurred after age 35. When we simultaneously controlled for parity, age at first birth, age at menarche, and the core set, the RR estimate from the logistic model was 1.7 (1.2, 2.4) for last birth over

age 35 relative to less than age 25. The RR was highest for the youngest age group, but differences by age were not significant. Results were similar when the analyses were restricted to those women having at least two births.

Breast feeding.—Among parous women, fewer of the cases than controls in each age group breast fed for 2 or more consecutive weeks. The overall RR estimate, after adjustment for age, age at first birth, and parity, was 0.6 (0.5, 0.8). Although the "protective" effect seemed independent of age at first birth and parity, no trend was seen with length of breast feeding. The effect of having breast fed was also significant (P=0.01) in the logistic analysis when we controlled for the core set, age at menarche, parity, and age at first birth.

Abortions and difficulty in conceiving.—No significant association between breast cancer and spontaneous abortions was seen, although slightly fewer of the cases reported 2 or more abortions.

Women were asked if they had difficulty in conceiving that was not due to their partner. For nulliparous women, 17 (46%) of 37 cases and 22 (28%) of 80 controls reported some difficulty. The age-adjusted RR associated with difficulty in conceiving with 95% CI was 2.6 (1.0, 6.6). For parous women, 61 (16%) of 379 cases and 68 (10%) of 680 controls experienced some problems in conceiving. The RR adjusted for age and age at first birth was 1.8 (1.1, 2.9). Using a logistic model in which we controlled for the core set, age at menarche, parity, and age at first birth, we found that difficulty in conceiving had a highly significant (P=0.002) effect with an RR estimate of 1.7 and no significant variation by age.

OC use.—A recent user of OC was defined as an individual having taken them within 1 year of diagnosis (for cases) or within 1 year of January 1977 (for controls). As shown in table 2, there was an increased risk associated with recent use in the age stratum 30–44. No clear trend emerged with length of OC use, however. At ages 30–44 the RR estimates were 1.3 for 1–4 years of use and 1.2 for 5 or more years of use. Among the small number of women aged 30–44 using OC for menstrual problems [10 cases (10%) and 17 controls (5%)], an increase in risk was suggested [RR=2.2 with 95% CI (0.8, 5.9)].

Menopausal status.—Menopausal status was categorized as premenopause, perimenopause, post-natural menopause, or post-surgical menopause. Perimenopausal women were excluded from analyses because of small numbers and the difficulty in obtaining an accurate determination of menopausal status. Women having a hysterectomy prior to experiencing symptoms of a natural menopause were classified as post-surgical menopause if both ovaries were removed. If neither or only one ovary had been removed or if women were uncertain as to their status, they were categorized as post-natural menopause if aged 60 or over and as unknown if under 60. Women having a hysterectomy following a natural menopause were classified as post-natural menopause. Table 2 shows that the RR of breast cancer for premenopausal women was higher than that for post-natural

menopausal women, which in turn was higher than that for post-surgical menopausal women. These results were unchanged when we controlled for the use of menopausal hormones. Table 2 also shows, among women with natural menopause, a significant linear trend of increased risk with later age at natural menopause in the two oldest age strata. The reverse trend in the age stratum 45–54 was not significant.

The statements of breast cancer patients relating to a previous hysterectomy and/or oophorectomy were checked for accuracy by a review of their medical records. This review showed that 89% knew the type of surgery and the number of ovaries removed; among bilateral oophorectorized women, only 5% were misclassified.

Family history of cancer.—Risks were elevated in women having a mother or any sister with breast cancer, with RR among women under age 55 slightly higher. The age-adjusted RR were 2.2 (1.3, 3.8) and 2.3 (1.4, 3.8) associated with breast cancer in the mother or a sister, respectively. The effect was not influenced by menopausal status, and no significant variation with age was seen in the logistic analysis. Similar estimates were obtained for a history of a mother or any sister with breast cancer when calculations were limited to women with and without a previous benign breast biopsy. A history of cancer other than breast cancer in the mother or any sister did not affect the risk of breast cancer (RR of 1.1 and 1.0, respectively).

Previous breast biopsy.—A positive association was seen between breast cancer risk and a previous biopsy for benign breast disease. There was little variation by age, the age-adjusted RR being 2.2 (1.6, 3.1), but the risk estimates varied according to age at menarche (being higher among women with late menarche), parity (being higher among women of low parity), and menopausal status (being higher among postmenopausal women). The association was not influenced by the use of OC.

Diabetes.—There were 23 (5%) cases and 31 (6%) controls who had diabetes. The age-adjusted RR estimate was 0.6 (0.4, 1.1) with no significant differences between the age strata.

Tonsillectomy.—The RR of breast cancer was elevated among women with a history of tonsillectomy. The RR increased steadily with age, exceeding twofold among women over 65 [RR=2.3 with 95% CI (1.3, 3.9)]. The risk estimates with the use of a logistic model in which we controlled for the core set, age at menarche, and parity showed a significant (P=0.05) overall excess and a similar trend with age.

Other variables.—No association with risk of breast cancer was found for mother's age at the subject's birth, breast size (as estimated from brassiere size), or previous appendectomy.

DISCUSSION

This population-based survey in an area where incidence is high at all ages revealed that the determinants of breast

TABLE 4.—*RR of breast cancer associated with age at first term birth and parity according to age at diagnosis*

cancer may differ between younger and older women. Certain factors were linked to increased risk at all ages, but others (including low parity and late age at first birth) seemed to affect only older women, while still others were primarily related to risk at younger ages. The differences with respect to age were often substantial. The risk of breast cancer among women with late (≥25) age at first birth and low (≤3) parity exceeded that among women with early (<20) age at first birth and high (>3) parity by sevenfold at older ages, whereas a slight deficit was observed among women under 45 years. There was a more than 50% reduction in the risk of breast cancer at ages 55–80 for women with early natural menopause, but an increased risk was not seen at ages 45–54 (suggesting a "lag" in the protective effect of early menopause). Some of the interactive effects observed may be chance findings due to the multiple comparisons made, but taken together the data on the variables studied revealed a combination of independent influences and complex interrelationships that often varied by age. The identification and quantification of these interactions may help in providing clues to the intricate causal pathways leading to the development of breast cancer.

Several new associations were found in this study. Breast cancer was linked to tonsillectomy, with the strength of the association increasing steadily with age and exceeding twofold among women over age 65. The finding is of concern in view of the rising frequency of this surgical procedure during the mid-1900's and raises an hypothesis worthy of testing in other settings. Also provocative is the increased risk associated with recent use of OC among women aged 30–44. There were, however, no concomitant excess among the smaller number of recent users at older ages, no significant increase associated with past use, and no trend with duration of use, suggesting that the association may be noncausal. Furthermore the different interview settings, with cases interviewed in clinics by nurses and controls interviewed in their homes by professional survey personnel, may have affected response to questions of a sensitive nature, such as birth control use (potential biases of this sort are discussed further below). Although case–control and cohort studies have generally revealed no overall association between breast cancer and OC use (*14*), recent observations raise concern. A record-linkage survey reported large (over fourfold) excesses among current OC users for premenopausal women aged 46–55 but not for women aged 31–45 (*15*); a case–control study of breast cancer in women under age 33 showed a twofold excess risk among those who had used OC for more than 4 years before their first full-term pregnancy (*16*); a cohort study of OC users in Great Britain noted a nonsignificant increase in risk of nearly threefold in women under age 35 (*17*).

Another new finding was the twofold significantly increased risk associated with high parity at ages 30–44, which was independent of other risk factors such as age at first birth. This finding contrasts with the decreased risk with high parity often reported in the literature and also observed in our population of women aged 45–80. The association at younger ages was even stronger when the last birth occurred after age 35 and parallels that seen in mortality statistics (*18*), with higher death rates among fertile women than single or infertile women under age 35 but lower rates among fertile women at older ages. The reversal suggests that while high parity may in the long term protect against breast cancer, factors associated with the greater number and lateness of births may promote the risk of breast cancer during the childbearing ages.

Most results from this survey are consistent with the consensus of those reported elsewhere (*19–21*). Of note is the pattern of increasing risk with later age at first birth, at older but not younger ages at diagnosis, similar to the pattern observed in another Canadian population (*5*), although the effect seemed limited to younger ages in two case–control surveys in the United States (*3, 6*). Most studies of breast cancer, however, are comprised mainly of older (≥50 yr of age) women and clearly show an increase in risk with late age at first birth (*19–21*). Familial clustering of breast cancer has been documented at all ages but is thought to differentially affect younger women (*22*); our data tend to follow this pattern, with increased risks seen in individuals for whom either a mother or sister had breast cancer. A surprising result was an apparent protective effect of breast feeding in all age strata, independent of age at first birth and parity. Some studies have suggested that prolonged lactation (>17 mo) may have a protective effect against breast cancer (*23*), but MacMahon et al. (*24*) and others have shown no consistent relationship between breast cancer and breast feeding. The associaton in our study may not be causal, since no trend with length of breast feeding was observed. The association with benign breast disease (indicated by a previous benign biopsy) was consistent across age groups, but further analyses of the link were precluded in our study because of lack of information on the timing and characteristics of the benign breast diseases.

Of concern to us in this study were the possible biases introduced by the different interview procedures for cases and controls and by the higher percentage of nonresponders among the controls. The different interview settings could influence responses to less objective questions and questions with more of a medical orientation (such as those concerning difficulty in conceiving and spontaneous abortions) but would seem unlikely to affect "hard" data (such as the age at birth of first child, number of children, history of tonsillectomy, and most other questions asked in the interview). The different times of interview, with cases being interviewed throughout 1976 and 1977 and controls in the fall of 1978, could result in differences for exposures that have changed rapidly over time. Few variables in our study, however, fall in this category, except possibly for the use of OC, since practices have fluctuated during the 1970's.

We were able to make some internal evaluation of potential interviewer differences by comparing responses for 45 breast cancer patients, who were not interviewed in the clinic for a variety of reasons but in their homes in the same manner as controls, with responses for the 565 patients interviewed in the clinics. The 45 patients are not necessarily a random selection of the incident cases and comprise a somewhat higher percentage of older patients than the clinic-interviewed series. Comparison of the questionnaire responses, however, generally revealed concordance. There were no significant differences except for country of birth (more home-interviewed cases were born in Canada or the United States, $P=0.08$) and age at first birth (the mean ages were the same, but clinic-interviewed cases had a lower age at first birth for the oldest age strata and a higher age at first birth for the youngest strata, $P=0.08$). The 2 groups of cases were of sufficient sample size to generally (depending on the frequency of the "exposure") detect differences between them on the order of 2.5-fold with reasonably high power ($>80\%$).

To assess the representativeness of the interviewed control sample, we compared certain characteristics of this group with population statistics taken from the 1971 Canadian census (*25*, *26*). Differences between the control sample and census data covering northern Alberta (census divisions 7–15) with respect to the percentage in any religious group were small ($<3\%$). Census data for parity were available for only the Prairie Provinces (Alberta, Saskatchewan, and Manitoba). The control sample differed from the census data primarily in the youngest age group, in which controls had generally lower parity (27% had parity >3 compared to 37% in the population statistics). This fact could account in part for the excess risk associated wtih high parity at younger ages but may also be simply a reflection of urban–rural differences (northern Alberta being more urban than the Prairie Provinces as a whole) and possibly changes in childbearing practices between 1971 and 1978.

We also made renewed attempts to interview the 238 of the 352 nonresponders (i.e., the 352 women selected in the original control target sample who were not interviewed) available for recontact. After current addresses were obtained, a brief questionnaire was mailed in January 1980. If the questionnaire was not returned, telephone contact and interview were attempted. There were 59 completed interviews; a total of 140 women could not be relocated, 31 refused, 4 were deceased, and 4 could not be interviewed for other reasons. Questions were asked of the nonresponders on year of birth, years in primary, secondary, university, and/or other school, country of birth, age at menarche, type of and age at menopause, age at first and last birth, parity, occurrence of a previous breast biopsy, and difficulty in conceiving. There were no significant differences between the responders and the 907 controls for any of these variables. None of the interviewed nonresponders had breast cancer.

In summary, there were certain limitations inherent in this case–control study of breast cancer that may have affected some of the comparisons made. Their influences on the majority of variables, however, seem likely to be small and cannot account for the marked effect of age at diagnosis on the risk associated with several variables, especially reproductive factors. The data are generally consistent with other observations suggesting a varying set of determinants of breast cancer affecting younger and older women (*1–6*), even though some risk factors are common to all age groups. In further etiologic studies of breast cancer, analyses by age group should help delineate factors and provide insights into multicausal and multistage mechanisms.

Cancer Incidence in the Republic of Panama, 1974–78[1,2]

William C. Reeves,[3,4] Plinio F. Valdés,[5] María M. Brenes,[3] Rosa C. de Britton,[5] *and* Claire F. B. Joplin[3,6]

ABSTRACT—Data were examined from the Panama National Cancer Register, which was created by the Panamanian National Oncology Institute in 1974 to record data on all histopathologically diagnosed cancers in the Republic. Age- and sex-specific incidence rates were summarized for all cancers registered between 1974 and 1978. The age-adjusted incidences of invasive cervical cancer (37.8/100,000 population), penis cancer (1.9/100,000), and oral cancer (male, 3.2/100,000; female, 3.7/100,000) were among the highest in the world. In addition, both male and female genital cancers were clustered in rural Herrera Province (age-adjusted incidence: cervix, 84.7; and penis, 4.3).—JNCI 1982; 68:219–225.

Tropical countries have historically devoted most of their health resources to the fight against infectious diseases. In countries such as Panama, with rapidly improving environmental and health standards, infectious diseases remain the principal cause of morbidity but not of mortality. In Panama, along with the population's increasing life-span, noninfectious chronic diseases are emerging as major health problems, as reflected in the documented cause-specific mortality rates. Cancer has been among the three principal causes of death since 1968 (*1*). The National Oncology Institute of Panama initiated a National Cancer Register in 1974 to document and quantify cancer incidence. This paper reports results gathered during the Registry's first 5 years.

METHODS

Beginning in 1974, the Panama National Cancer Register recorded all histologically diagnosed cancers. The secretary of the Registry routinely visited each certified pathologist in Panama and reviewed all histopathology reports. We made no attempt to register individuals with only clinically diagnosed malignancy nor have we included people certified as dying of cancer, but without histopathologic evidence. For each newly diagnosed cancer we recorded the patient's name, age, sex, hospital or clinic chart number, as well as the date of diagnosis, anatomic site and type of cancer coded according to ICD-9 (*2*), and town where the tissue specimen was obtained (this allowed a crude estimation of residence). Register data was maintained on a General Automation SPC 16/65 minicomputer system with the use of the Conversational Computer Statistical System (*3*). Duplicate registration was monitored by checking the patient's name and hospital or clinic chart number. When necessary, specific charts were retrieved to verify information.

We obtained 1974–78 population data from the Census Bureau, Contraloria General de Panama. Panama maintains an extremely accurate and current census. A complete national census was taken in 1970; a second census in 1975 counted the voting population for the Canal Treaty ratification; a third census in 1978 documented the voting population to elect the House of Representatives; the fourth complete census in 10 years occurred in May 1980. Activities throughout the entire country ceased on census day and people were required to remain at home until enumerated. The Government made particular effort to completely tabulate the rural population. To compare Panama's cancer incidence rates with data reported by other countries, we adjusted the age to the standard world population (*4*). We used the Mantel-Haenszel method (*5*) to contrast age-specific interprovince incidence rates.

Cancer data from Darien Province or Comarca de San Bias are not reported. These areas are extremely isolated and have limited health care facilities. Data from Chiriqui and Bocas del Toro Provinces were combined.

RESULTS

The Republic of Panama is a rapidly developing tropical Latin American Country located 7° north of the equator. At the chronological midpoint of this report in 1976, the population of Panama was estimated as 1,718,700; with its 77,082-km^2 surface area, Panama had an overall population density of 24.9 persons/km^2.

Panama's public health system operated clinics and hospitals in each province (*1*). In 1976 there were 7.9 physicians per 10,000 population. This ratio ranged from 19.3 per 10,000 in the capital city to 2.7 per 10,000 in the most remote province. In 1976 Panama had 330 health care centers (30 hospital medical centers, 12 hospitals, and 288 health centers with outpatient clinics) or 1.9 health care centers per 10,000 inhabitants. Panama's cause-specific mortality rates reflected her excellent health care delivery sys-

tem; ischemic heart disease, cancer, accidents-suicide-homicide, and stroke have constituted the principal causes of death since 1968 (*1*).

The average annual male and female age-specific incidence rates for all cancers registered during the period 1974–78 are shown in tables 1 and 2. Invasive cervical cancer was the most frequently diagnosed malignancy and accounted for 33% of female cancers. In addition, Panama's invasive cervical cancer incidence rate was higher than that in most of the countries in the World Health Organization and IARC registry programs (table 3) (*6*). Penis cancer also had a unusually high incidence compared to that of other areas (table 4).

Panama's cervical cancer incidence varied by province (text-fig. 1). Women living in Herrera Province had a risk of invasive cervical cancer 1.6 times that of women from Panama Province and 4.5 times more than the combined remaining provinces (overall rate 18.8 cases per 100,000). These relative risks remained constant between 1974 and 1978. Herrera had significantly greater in situ and invasive cervical cancer incidence rates than Panama Province ($P<.001$) and both diseases were significantly more frequent in Panama Province than in the combined other provinces ($P<.001$) (tables 5 and 6).

Penile cancer incidence also varied by province (text-fig. 2). Men from Herrera had a 1.7 times greater penile cancer incidence than that of males diagnosed in Panama Province and 3.4 times the risk of men in the combined other provinces (1.27 per 100,000). Since only 52 such cancers occurred during the study, differences in annual incidence were not apparent.

In addition to having a high overall rate, women from

[b] Incidence per 100,000 population adjusted to standard world population.

Herrera developed invasive cervical cancer at an unusually young age (table 5). The Herrera invasive cervical cancer incidence among 20–39-year-old women was several times greater than that for the rest of the country. The age distribution of in situ carcinoma was similar throughout Panama (table 6), and women younger than 50 years were involved. Penis cancer mainly involved older men, and age-specific incidence rates were similar throughout the country.

DISCUSSION

The Panama National Cancer Register had two limitations. First, because it enumerated only histologically diagnosed disease, true cancer incidence was underestimated. However, limiting registration to confirmed diagnoses eliminated local variation in clinical diagnostic criteria. Histologic standards were constant because most biopsies were

evaluated at two major hospitals. Therefore, we are confident that unusually high observed rates accurately reflected the real situation. The second limitation was lack of epidemiologic data, such as race, occupation, residence, and birthplace, and follow-up. Most importantly, residence was estimated on the basis of the province the biopsy came from. However, since many people travel to Panama Province for diagnosis and treatment, cancer incidence there was overestimated.

Cancers of the uterine cervix and penis occurred at high incidence rates. Cancers of the mouth (ICD codes 143–145) also had extremely high age-adjusted rates: female oral cancer incidence 3.7 per 100,000 population, was third in the world after Singapore (Indians 16.9/100,000) and Bombay (5.4/100,000), while the male rate of 3.2 per 100,000 was only exceeded by 16 of the 80 IARC Registers (*6*).

None of the other frequently occurring Panamanian cancers presented striking epidemiologic differences when compared to areas that collaborate in the IARC Cancer Registry Program (*6*). In most instances, the standardized Panamanian cancer incidence rates were slightly lower than those reported from other Latin American and Caribbean populations.

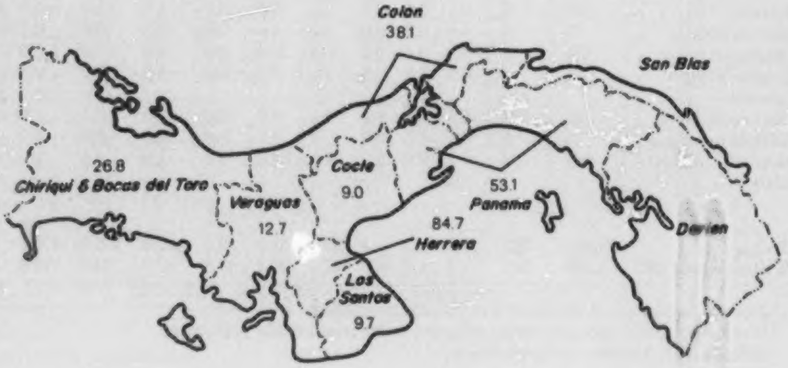
Cervical cancer not only constituted the most frequently diagnosed malignancy in Panama, but its age-adjusted incidence ranked among the highest reported in the world. This fits into the worldwide epidemiologic picture of cervical cancer. Cervical cancer mortality rates have steadily decreased in industrialized countries (*7*) and concurrently increased in developing countries (*8*). Currently the Caribbean area of Latin America has the highest documented cervical cancer incidence among the developing countries (*9–12*). The three areas reporting a higher cervical cancer incidence than Panama (Cali, Colombia; Recife, Brazil; Kingston, Jamaica) have many cultural and ethnic similarities to Panama.

Significant differences between interprovince cervical



TEXT-FIGURE 1.—Invasive cervical cancer incidence in Panama, by province, age adjusted to standard world population.

cancer incidence rates also existed. Women from Herrera had 1.6 times the risk of developing invasive cervical carcinoma compared to women from Panama Province, and a 4.5-times greater risk than that of women from the combined other Provinces. No area in the world has documented a higher cervical cancer incidence than Herrera, and we know

TEXT-FIGURE 2.—Penis cancer incidence in Panama, by province, age adjusted to standard world population.

that the histopathologically based Panama National Cancer Register not only underenumerated the actual number of cases but also was biased to classify many women from Herrera as residents of Panama Province.

Cancer of the penis also presented an extremely high incidence in Panama between 1974 and 1978 and was clustered in Herrera Province. Although rare in most of the world, cancer of the penis constitutes a public health problem in several developing countries of South America and the Caribbean (*6, 13*).

A relationship between carcinoma of the cervix and that of the penis was suggested by data from Puerto Rico (*14*) but has not been verified in other studies (*15, 16*). Some investigators (*17, 18*) have hypothesized a relationship between "high risk males" and cervical cancer, and this may be related to the occurrence of penile cancer. However, cancer of the penis and perhaps of the cervix may reflect other factors such as general hygiene.

We have evaluated several possible confounding factors but none of them seemed to account for this provincial clustering. Errors in enumerating the denominator, the population at risk, do not account for our findings. As stated previously, the Republic of Panama maintains an extremely complete and current census. The government has a special interest in delineating the rural population, which is stable and has not been affected by large-scale immigration. In addition, we eliminated Panama's two isolated undeveloped provinces from our analysis.

Similarly, the high invasive cervical cancer rate observed in Herrera was not due to bias in interpreting the tissue specimens. Since only Panama, Colon, and Chiriqui Provinces had pathology laboratory services between 1974 and 1978 (*19*), all histologic material from Herrera and the other outlying provinces was sent to Panama City and was evaluated (irrespective of origin) at either Santo Tomas or Seguro Social Hospital. Both hospitals have active pathology residency programs and maintain frequent interchange with pathologists at major U.S., South American, and European medical schools. The higher cancer incidence rates attributed to Panama Province were due to the many patients who were referred to hospitals in the capital for diagnosis and treatment.

Finally, differences in medical care could not have accounted for the extremely high rates of cervix and penis cancer seen in Herrera. Herrera was similar to other rural provinces with respect to physicians' services: physician-to-population ratio, availability of primary health care facilities, and overall patient utilization of such facilities (*19*). Moreover, if an unusually high awareness of cancer as a problem had prevailed, or an exceptionally aggressive group of gynecologists had worked in Herrera, the rates of other cancers should have been high also, but this was not the case (table 7).

Women living in Herrera were more likely to have Papanicolaou's (Pap) smears than women from other provinces. Between 1974 and 1978, an average of 9.9 per 100 Herrera women over 20 years of age had a Pap smear as contrasted to 6.4 per 100 in Panama Province and 4.6 per 100 in the combined other provinces. The extent to which Herrera's more intensive Pap smear program accounted for the increased invasive cervical cancer incidence cannot be estimated using currently available data (*20*).

Table 7.—*Incidence per 100,000 adjusted to the standard world population of the most common cancers in males and females, Panama 1974–78*

Site	Males			Females		
	Entire country	Herrera province	Panama province	Entire country	Herrera province	Panama province
Skin	16.9	11.5	26.8	14.7	13.2	23.5
Breast	—	—	—	14.4	5.5	24.8
Prostate	14.4	6.5	25.8	—	—	—
Stomach	10.4	9.4	17.2	6.1	5.2	10.3
Corpus uteri	—	—	—	4.1	1.7	6.7
Ovary	—	—	—	3.1	2.1	5.3
Other female genitals	—	—	—	2.4	3.1	3.8

Herrera also demonstrated a unique age-specific cervical cancer profile. Herrera women between 20 and 39 years of age had a disproportionately high invasive cervical cancer risk. In the remainder of Panama, and the rest of the world, women older than 40 manifest the highest rates. This may imply that young women from Herrera were exposed to unique risk factors (*21, 22*). An understanding of these risk factors would not only contribute to the basic epidemiology of cervical cancer but would also allow development of effective local cancer prevention programs.

To explore this problem in more detail, we are currently updating the histologic National Cancer Registry to an expanded internationally standardized format similar to that recommended by the IARC (*23*). This will include the cancers diagnosed clinically as well as histologically, and contain informations such as birthplace, town of residence, racial–ethnic group, occupation–socioeconomic status, and obstetric–gynecologic history.

Phase I–Phase II Trial of *N*-Phosphonacetyl-L-Aspartic Acid Given by Intravenous Infusion and 5-Fluorouracil Given by Bolus Injection[1,2]

Charles Erlichman,[3,4] Ross C. Donehower,[5] James L. Speyer,[6] Ray Klecker,[7] *and* Bruce A. Chabner[7]

ABSTRACT—A phase I clinical trial of *N*-phosphonacetyl-L-aspartic acid (PALA) and 5-fluorouracil (FUra) was performed on 30 patients. PALA was given as a 15-minute iv infusion once daily for 5 days, and FUra was given as a bolus injection on days 2, 3, 4, and 5. Cycles of treatment were repeated every 3 weeks. Dose-limiting toxicity was manifested by stomatitis and diarrhea. Skin rash was observed also but was not dose limiting. No consistent hematopoietic or renal toxicity was observed. Seventeen patients with disseminated metastatic melanoma and measurable disease were evaluated for response. One partial response was seen; however, the response was associated with significant toxicity, and the treatment could not be repeated. Stable disease was observed in 3 patients with melanoma, 1 patient with colon carcinoma, and 1 patient with ovarian carcinoma. Our findings suggest that the clinical activity of PALA and FUra given according to the above schedule for melanoma is less than 25% ($P<0.05$). Pharmacokinetic studies of FUra revealed no consistent effect of PALA pretreatment on FUra disappearance in plasma. The mean FUra elimination half-life in plasma was 7.11±0.84 minutes (SEM), which is no different from that reported for FUra alone. The recommended doses on this schedule for phase II studies are 1,000 mg PALA/m^2/day iv daily for 5 days and 200 mg FUra/m^2/day iv on days 2, 3, 4, and 5—JNCI 1982; 68:227–231.

The use of combination chemotherapy has become commonplace in the treatment of many neoplastic diseases. In general, drugs have been combined on the basis of their single-agent activity and their lack of overlapping toxicity for normal tissues. Some consideration also has been given to the ability of drugs to act at different phases of the cell cycle. Increasing interest is now being directed to drug combinations designed to take advantage of biochemical interactions at the cellular level. We report here a phase I trial of a combination of PALA and FUra, which was designed with the biochemical mechanisms of these agents in mind.

PALA, a potent inhibitor of aspartate transcarbamylase, acts to inhibit de novo pyrimidine biosynthesis, as demonstrated in several murine solid tumors (*1, 2*). PALA has undergone extensive phase I (*3, 4*) and phase II trials (*5–7*) in humans over the last few years, but this agent has shown little clinical activity. FUra, a synthetic pyrimidine base analog, has been widely used in clinical chemotherapy for more than 20 years. In the cell, FUra is converted enzymatically to nucleotides. 5-Fluorouridine triphosphate is incorporated into RNA, and 5-fluorodeoxyuridine monophosphate potently inhibits cellular thymidylate synthetase. Pretreatment with PALA before FUra administration could result in increased FUra nucleotide formation, inasmuch as PALA has been shown to decrease intracellular pyrimidine nucleotide pool size in some cell lines (*8*), and could result in less competing substrate for FUra conversion to nucleotides, incorporation into RNA, and inhibition of thymidylate synthetase. Additionally, inhibition of the de novo pathway for pyrimidine biosynthesis by PALA might result in increased cellular levels of PRPP because of decreased use by this pathway. Drugs that increase PRPP levels, such as methotrexate, have been shown in vitro to result in enhanced FUra nucleotide formation (*9*).

In support of this hypothesis that pretreatment with PALA would enhance FUra activity, animal studies have shown that PALA and FUra together have greater antitumor activity in CD8F1 mammary carcinoma (*10*), colon 38 and 26 carcinomas, Lewis lung carcinoma, and M5076 carcinoma than do single agents (*11*). On the basis of this hypothesis, a study of PALA and FUra was performed on patients with extensive malignant disease. A dose schedule was chosen that included pretreatment with PALA, to decrease intracellular pyrimidine nucleotide levels before administration of FUra.

MATERIALS AND METHODS

This phase I–phase II trial was conducted cooperatively by the Medicine Branch and the Clinical Pharmacology Branch of the National Cancer Institute. Entered in the study were 30 patients, 26–68 years old. The male:female

ratio was 1.6:1. The presence of cancer in all 30 patients was pathologically confirmed: 18 had melanomas, 8 had carcinomas of the colon, 2 had carcinomas of the ovary, 1 had a sarcoma, and 1 had carcinoma of the pancreas. Prior therapy with other chemotherapeutic agents (mean, two drugs) had been administered to 24 patients; 3 patients with carcinoma of the colon and 1 patient with carcinoma of the ovary had had prior FUra chemotherapy. The patient performance status was 30-90 on the Karnofsky scale; 24 of 30 had a performance status greater than or equal to 50.

Every 3 weeks patients received a daily 15-minute iv infusion of PALA for 5 consecutive days. FUra was given as a bolus injection shortly after completion of the PALA infusion on days 2, 3, 4, and 5. This dose schedule was chosen on the assumption that 1-day pretreatment with PALA would significantly decrease the levels of intracellular pyrimidine nucleotides prior to administration of FUra. Dose escalation for new patients was permitted after a minimum of 3 patients had completed 2 therapy cycles. In the absence of known cumulative toxicity for either drug, dose escalation was allowed for patients who had successfully completed a therapy cycle with no toxicity. Two drug escalation programs were used. Initially, the PALA dose was 1,500 mg/m^2/day for 5 days, and FUra was increased from 100 to 150 to 250 mg/m^2/day. The PALA dose was then decreased to 1,000 mg/m^2/day, and FUra was escalated from 150 to 200 to 250 mg/m^2/day. The 6 patients who received 700 mg PALA/m^2/day and 150 mg FUra/m^2/day had developed significant toxicity at a higher dose level in this trial. Patients were considered to be assessable for acute toxicity if they completed one course of therapy.

Skin and gastrointestinal toxicities were graded 1+ to 3+ according to the following criteria: Patchy areas of skin involvement were considered 1+, generalized skin involvement was graded 2+, and patients experiencing generalized exfoliation were assigned 3+. Patients who had loose bowel movements (<4 movements/day and none at night) or minimal stomatitis were considered to have 1+ gastrointestinal toxicity. Frank diarrhea (>4 movements/day) and/or stomatitis, which was uncomfortable but still permitted oral intake of food, was graded 2+. A 3+ gastrointestinal toxicity was assigned to patients having diarrhea with guaiac-positive stool and/or severe stomatitis associated with an inability to ingest any liquids or solids.

Pharmacologic studies were performed on selected patients at dose levels of 100, 200, and 250 mg FUra/m^2. By means of a high-pressure liquid chromatography technique (*12*), drug levels in plasma were monitored for 2 hours after the FUra iv bolus injection (*12*).

RESULTS

Renal function before therapy, as indicated by 24-hour creatinine clearance, was assessed in 22 patients: 14 had normal renal function (clearance ≥70 ml/min), 7 had moderate impairment of renal function (clearance <70 but ≥40 ml/min), and 1 had marked renal impairment (clearance <40 ml/min). In 8 patients for whom information on creatinine clearance was not available, the blood urea nitrogen was normal in all, and serum creatinine was less than 1 mg/100 ml in 6. Serum creatinine values of 1.3 mg/100 ml were recorded for 2 patients. The total bilirubin level in all 30 patients was normal. All patients except 2 had WBC counts of 3,500 or more/mm^3. The WBC counts for these 2 were 3,200 and 3,100/mm^3. All patients had platelet counts greater than 100,000/mm^3.

1,500	100	2	4
1,500	150	4	6
1,500	250	3	3

[a] Due to dose escalation in some patients, the total number is >30.

One patient died before completion of 1 cycle of therapy due to progression of the disease and was not included in toxicity evaluations. For the remaining 29 patients, the dose levels evaluated and the number of patients and therapy courses administered at each level are summarized in table 1. Six patients received 1 cycle of therapy only, 17 patients received between 2 and 5 cycles, and 5 patients received between 6 and 10 cycles. One patient received more than 14 therapy cycles.

The major clinical toxicities affected the skin and gastrointestinal tract and are summarized in tables 2 and 3. Skin toxicity was manifested most commonly by a macular, erythematous eruption that occasionally was pruritic. It usually began on days 5-8 of a cycle and was resolved in approximately 10-14 days. Skin toxicity did not occur consistently with each cycle. Prior chemotherapy or radiotherapy did not appear to predispose patients to skin toxicity. Although skin toxicity was a common occurrence, at none of the dose levels evaluated was it dose limiting.

Gastrointestinal toxicity was the dose-limiting toxicity for the PALA-FUra combination used in this study. The major symptoms were mucositis and severe diarrhea. All 3 patients treated at a dose level of 1,500 mg PALA/m^2/day and 250 mg FUra/m^2/day developed severe mucositis and diarrhea with guaiac-positive stool. One patient treated at 1,500 mg PALA/m^2/day and 250 mg FUra/m^2/day became hypovolemic, secondary to fluid loss from diarrhea, and developed renal failure. Careful management of these complications reversed the renal failure and the patient recovered.

At 1,500 mg PALA/m²/day and 150 mg FUra/m²/day, 2 patients developed significant gastrointestinal toxicity manifested by prolonged oral mucositis. At 1,000 mg PALA/m²/day and 200 mg FUra/m²/day, most episodes of toxicity were relatively mild and tolerable. However, 2 of 59 therapy courses were associated with significant mucositis, which varied from angular stomatitis to complete oral mucosal ulceration. The mucositis began most commonly on day 4 and lasted 2–14 days. Diarrhea usually began during the second week of a cycle and was associated with occasional cramping. Gastrointestinal toxicity appeared to depend on the dose of FUra given with 1,500 mg PALA/m², but this relationship was not demonstrated when the PALA dose was 1,000 mg/m². Three patients complained of a gritty sensation in the eyes and photophobia. Two of these had obvious conjunctivitis. None of the three had any visual acuity disturbance, and ophthalmoscopic examination did not reveal any retinal abnormalities.

Hematologic toxicity was assessed by measurement of WBC and platelet counts during the course of therapy (table 4). For 52 of 98 therapy courses, nadir blood counts were available for assessment of hematologic toxicity. No patient developed a platelet count of less than 50,000/mm³. Five courses of therapy were associated with a fall in platelet counts to less than 100,000 but greater than 50,000/mm³. After receiving 1,500 mg PALA/m²/day and 100 mg FUra/m²/day, 1 patient developed a platelet count of 73,000/mm³. A second patient on 2 cycles of 1,000 mg PALA/m²/day and 250 mg FUra/m²/day developed platelet counts of 95,000 and 59,000/mm³. This patient had platelet counts of 74,000 and 59,000 when treated with 2 cycles at 1,000 mg PALA/m² and 200 mg FUra/m²/day. The WBC nadir was less than 2,000 in 2 patients both treated with 1,000 mg PALA/m²/day and 200 mg FUra/m²/day. One of these individuals had been treated previously with cisplatin, chlorozotocin, and BCG. The other patient had received no previous therapy.

While receiving PALA–FUra therapy, 5 patients developed neurologic abnormalities. The 2 patients who had generalized seizures on 1,000 mg PALA/m²/day and 200 mg FUra/m²/day were simultaneously documented to have central nervous system metastases. One patient treated with 1,500 mg PALA/m²/day and 250 mg FUra/m²/day had focal seizures during a period when he was uremic and had a serum creatinine of 12.2 mg/100 ml. In 2 patients in whom bizarre affects and thought disorders were observed, no underlying central nervous system lesions were found. In 1 of these patients treated with 1,000 mg PALA/m²/day and 150 mg FUra/m²/day, the abnormal behavior was resolved when chemotherapy was suspended. However, in the other who received 1,500 mg PALA/m²/day and 150 mg FUra/m²/day, no improvement occurred after therapy was stopped.

Due to disease progression, 24 patients were removed from the study, and 2 patients died from the disease during the study. Two were removed from the study after they refused further therapy. Two at this writing have stable disease and continue in the study. The 17 patients with pathologic diagnosis of melanoma were treated at adequate doses that produced mild but significant toxicity, and all had measurable disease. No patient had a complete response. One developed a partial response with greater than 50% decrease in a skin nodule and lung metastases. Another patient had a mixed response: a greater than 50% decrease in the size of skin lesions but developed liver metastases on therapy. Three patients with melanoma were considered to have stable disease for 2 and 3 months. None of these patients had had previous FUra therapy. One patient with ovarian carcinoma, who had previously received FUra, was stable for 10 months, and another with colon carcinoma was stable for 4 months.

Pharmacologic studies were performed on 9 patients. Maximum plasma FUra levels were 3.27 m*M* at a dose of 250 mg/m². Plasma FUra levels dropped below the level of assay sensitivity (5×10^{-8} *M*) within 60 minutes. In some patients, a distinct bi-exponential decline could not be

clearly defined because of difficulties in obtaining adequate numbers of early samples during this distribution phase (text-fig. 1). Therefore, individual FUra profiles were analyzed in terms of a pharmacokinetic, one-compartment, open model similar to that of MacMillan et al. (*13*). The dose levels, plasma FUra elimination rate constant k, plasma FUra elimination $t_{1/2}$, and the AUC are summarized in table 5. The mean $t_{1/2}$ was 7.11±0.84 minutes (SEM). The mean AUC values obtained in this analysis did not increase linearly with dose, but a rapid nonlinear increase in the mean AUC level was observed for those patients treated with 250 mg FUra/m²/day (text-fig. 2).

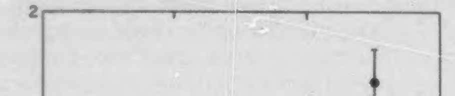
DISCUSSION

An initial trial of PALA given as a 15-minute daily iv infusion for 5 days and FUra on days 2, 3, 4, and 5 as a bolus injection, repeated every 3 weeks, demonstrated dose-limiting toxicity to gastrointestinal mucosa. The major toxicity of PALA as a single agent is manifested in the skin and gastrointestinal organs, whereas FUra when given by bolus injection most commonly results in myelosuppression. However, gastrointestinal and skin toxicity can occur with FUra even when given by bolus injection. Therefore, it is difficult to attribute the toxicity observed in this study to either agent alone. In 2 patients, neurotoxicity occurred that was not explained by causes other than drug administration. Inasmuch as neurologic abnormalities secondary to administration of PALA have been reported (*14*), and because FUra is known to occasionally cause neurologic problems, the neurotoxicity of the 2 patients may be due to both drugs. Conjunctivitis and photophobia after PALA administration, which occurred in 3 patients, previously were not reported (*3, 4*), but these conditions may occur after FUra administration.

This study involved the treatment of numerous patients with melanoma because other clinical trials were being conducted at the time for patients with this diagnosis at the National Cancer Institute. Patients who failed those trials were eligible for our study. A partial response was experienced by 1 of 17 patients with melanoma. However, this patient, treated with 1,500 mg PALA/m²/day and 250 mg FUra/m²/day, developed severe diarrhea with associated hypovolemia and subsequent acute tubular necrosis. Careful management reversed the renal failure and the patient recovered, but subsequent courses of treatment with PALA and FUra could not be administered to him. Our findings suggest that this particular dose schedule for PALA and FUra would result in less than a 25% response rate (P<0.05) for patients with melanoma and, therefore, would not be a useful combination for clinical therapy of melanoma.

The FUra pharmacokinetic studies on patients treated with PALA and FUra suggest two points: *a*) The plasma elimination $t_{1/2}$ of 7.11 minutes that we observed is not different from that reported by others in single-agent studies (*13*). This implies that any enhanced toxicity observed for the PALA-FUra combination was not due to a change in plasma clearance of FUra by PALA. Because PALA is excreted primarily by a renal mechanism and is not highly protein-bound and FUra is primarily metabolized, pharmacokinetic interaction between these agents in plasma would not be expected. Such a conclusion is supported by our studies. Therefore, it is more likely that any enhanced toxicity is the result of an interaction at the cellular level. *b*) A saturable mechanism in the elimination of FUra is suggested by the nonlinear relationship between the AUC and the administered FUra dose. This interpretation must be made cautiously because of the small numbers of patients treated at each dose level and the wide variation in the calculated AUC; however, this interpretation agrees with suggestions made in other reports (*15, 16*).

The dose schedule in this study was chosen to take advan-



TEXT-FIGURE 2.—Plot of mean AUC vs. FUra dose level. *Error bars* represent SEM.

tage of the mechanism proposed for PALA and FUra interaction at the cellular level. We had previously noted that on the PALA schedule of a 15-minute infusion daily for 5 days, aspartate transcarbamylase levels in leukocytes were significantly depressed within 24 hours of the first dose (*17*). If similar changes occur in other tissues, pyrimidine nucleotide levels would probably decrease in parallel by 24 hours after the first dose of PALA. Addition of FUra at that time could result in metabolism of this pyrimidine analog to active metabolites at a rate greater than that normally observed. However, a therapeutic benefit of this PALA-FUra dose schedule was seen in only 1 patient with melanoma. Other investigators using other schedules have reported responses in colon carcinoma, large cell carcinoma of the lung, fibrous histiocytoma, and sarcoma (*18, 19*). Although we found very limited activity of this drug combination in patients who had received prior chemotherapy for metastatic melanoma, phase II studies with other dose schedules may be warranted on patients with other malignant diseases responsive to FUra. A schedule that involves PALA and FUra administration by continuous infusion may be more efficacious than the one used in this study. Such a schedule may allow more incorporation of FUra into RNA throughout the cell cycle. For future phase II studies, we recommend 1,000 mg PALA/m^2/day given iv over a period of 15 minutes for 5 days and 200 mg FUra/m^2/day given by bolus injection on days 2, 3, 4, and 5.

Phytohemagglutinin or Pokeweed Mitogen Induction of In Vitro Colony Formation by T-Cells From Patients With Chronic Lymphocytic Leukemia [1,2,3]

Vito Pistoia,[4] Arcangelo Nocera,[4] Riccardo Ghio,[5] Paola Minale,[4] *and* Manlio Ferrarini[4,6]

ABSTRACT—The colony-forming capacity of peripheral blood T-cells isolated from B-cell chronic lymphocytic leukemia patients was studied and compared with that of peripheral blood T-cells isolated from 2 groups of normal controls (young and aged healthy donors). Upon stimulation with phytohemagglutinin or pokeweed mitogen, T-cells from both the patients and the controls developed into colonies but only in the presence of the appropriate conditioned media. When the responses of the 3 groups were compared, no statistically significant differences were detected. However, the number of patients who failed to respond to phytohemagglutinin was larger than that of normal controls. Studies on a selected group of patients demonstrated that such unresponsiveness was unrelated to the presence of suppressor cells or to inadequate conditions used for stimulation in culture. Rather, this unresponsiveness may be connected with an intrinsic T-cell defect present in certain B-cell chronic lymphocytic leukemia patients.—JNCI 1982, 68:233–237.

B-cell CLL is a lymphoid cancer derived from the proliferation of a single clone of B-lymphocytes arrested at early stages of maturation and incapable of differentiating further into more mature cells (*1*).

In recent years the question has been raised whether or not T-cells from B-cell CLL patients may be responsible, at least in part, for the poor B-cell maturation; this problem has been investigated in several in vitro experimental systems (*2-8*).

Colony formation in semisolid media represents a most valuable tool for the study of both the proliferative and clonogenic capacities of T-cells (*9-11*). Furthermore, this in vitro technique has been progressively modified so that it is now possible to investigate the function of T-cells independently of the influence of any other accessory cell from the same subject. The present study deals with the colony-forming capacity of T-cells from B-cell CLL patients and shows that these cells do not behave differently from those of normal subjects.

MATERIALS AND METHODS

Patients.—Twenty-one patients aged 45–79 years (mean, 65 yr old) were studied. All had diagnoses of CLL confirmed by both clinical and histologic criteria. The white blood cell count ranged from 20,000 to 400,000 cells/mm^3 with a minimum of 70% lymphocytes.

According to the Rai classification (*12*), 6 of the patients had CLL in stage 0; 4, in stage 1; 3, in stage 2; 3, in stage 3; and 5, in stage 4. Most peripheral blood cells ($\geq$80%) had monoclonal membrane immunoglobulins in 20 of 21 patients, as assessed by immunofluorescence (*13*). In the remaining patient, the B-cell nature of the malignant cells was documented by their capacity to form rosettes with mouse red blood cells (*14*) and with antibody- and complement-coated erythrocytes (*15*).

None of the patients had serum monoclonal components or a positive Coombs' test. All but 5 patients had received treatment with chlorambucil before testing. For controls 28 normal healthy volunteers were used. They were subdivided into 2 groups: Control group I consisted of 13 individuals aged 21–35 years (mean, 28 yr old), whereas control group II was comprised of 15 individuals aged 45–72 years (mean, 62 yr old).

Cell separation.—MNC were separated from heparinized peripheral blood on F–H gradients. AC were removed from normal cell suspensions by adherence to plastic flasks. T-cells were isolated from MNC by rosetting with E_N, followed by F–H density gradient centrifugation (*16*). The rosettes in the pellets were passed on F–H gradients up to five times in the case of CLL or three times in the normal controls. E_N were lysed with ammonium chloride. The proportions of E_N rosettes in the purified suspensions were 96–98% and 85–90% for the normal subjects and the CLL patients, respec-

tively. T_G were removed from unfractionated T-lymphocytes by rosetting with ox red blood cells coated with rabbit IgG anti-ox antibodies. The rosettes were separated from the nonrosetting cells on F–H density gradients (*16*).

Preparation of CM—Two different CM were used. The first one was used for the PHA-stimulated cultures, whereas the other was employed in the PWM-stimulated cultures. The reasons for the use of different CM will be apparent below and have already been discussed in part previously (*17–19*).

1) AC CM: MNC, 1×10^6, were incubated in RPMI-1640 medium supplemented wtih 10% fetal calf serum in plastic flasks at 37°C for 1 hour. Non-AC were removed and AC were washed three times and cultured in the same medium at 37°C for 48 hours. CM were dyalized against phosphate-buffered saline (4 hr) and distilled water (24 hr), filtered, and stored at −20°C (*17*).

2) PWM-stimulated MNC CM: Tonsillar MNC were cultured for 48 hours at a concentration of 7×10^6/ml in RPMI-1640 medium supplemented with 10% AB serum and PWM at a final concentration of 1:50. CM was recovered, filtered, and stored at −20°C. AC CM and MNC CM were titrated according to the ability to support colony formation by purified T-cells and used at the optimal concentration.

Cell cultures.—Isolated T-cells were plated in semisolid medium with the use of a two-layer agar system, according to a modification of the method of Sachs (*20*). In 35-mm petri dishes cells were seeded in 1 ml of 0.4% agar, RPMI-1640, and 20% heat-inactivated AB serum over a 1-ml underlayer containing 0.5% agar, RPMI-1640, 20% AB serum, 6×10^6 human red blood cells, 5×10^{-5} *M* 2-mercaptoethanol, and 0.03 ml mitogen (PHA-M or PWM). CM were usually included in the underlayers. Their concentration (determined by preliminary titration experiments) ranged from 10 to 25% of the total volume of the agar. CFU-C, BFU-E, and CFU-E assays were performed according to published methods (*21, 22*). Cultures were incubated in a fully humidified atmosphere with 5% CO_2.

Statistical analysis.—The results were statistically analyzed by Student's *t*-test on logarithmically transformed data, the chi-square test with Yates' continuity correction, Fisher's exact probability test, and the nonparametric Mann-Whitney U test.

RESULTS

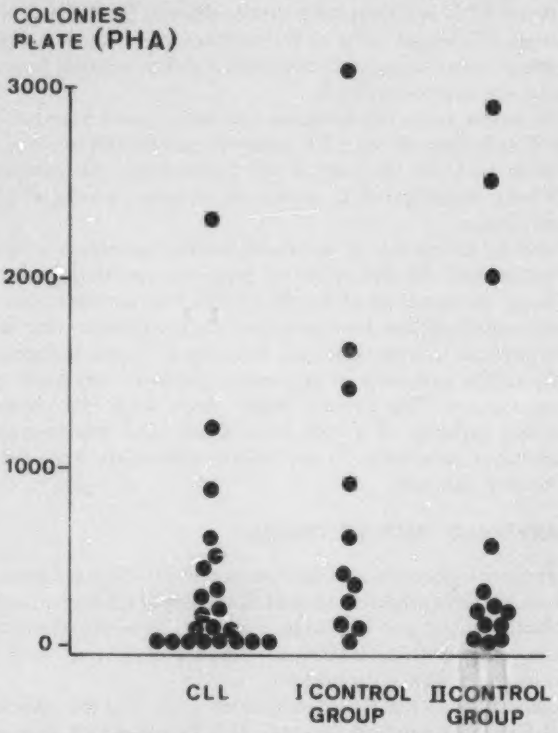
PHA Induction of Colony Formation by CLL T-Cells

T-cells from peripheral blood of CLL patients and the 2 control groups were tested for colony formation with the use of PHA as a mitogen. Preliminary experiments demonstrated that normal T-cells when cultured alone formed very few or no colonies. However, their colony-forming ability was raised to the values obtained with unseparated MNC by the addition of AC CM. Consequently, all of the T-cell cultures were supplemented with AC CM. With this technique colonies appeared after 72 hours and reached their maximum number after 6–7 days. Most of the colonies grew on top of the agar, whereas only a few (≈10%) developed inside the agar.

Since control studies demonstrated a strong GM-CSA in the AC CM, one could argue that the colonies detected in the purified T-cell fractions were not of lymphoid origin and could likely represent myeloid cells. However, to develop they had an absolute requirement for the presence of PHA. This requirement is different from that observed for the colonies of other lineages that grow in the presence of the GM-CSA (or erythropoietin) only. Moreover, specific tests for CFU-E, BFU-E, and CFU-C on purified normal T-cells failed to detect any colony formation. The same tests performed on CLL patients' purified T- or B-cells gave identical results (data not shown). Finally, separation studies on normal peripheral blood cells showed that CFU-E, BFU-E, and myeloid CFU-C precursors fractionated within the non-T–non-B cells (Ghio R, Pistoia V, Nocera A, and Ferrarini M: Manuscript in preparation).

Text-figure 1 shows the responses of T-cells from patients and those from normal controls. Statistical analysis of the data with the Mann-Whitney U test did not demonstrate a significant difference in the colony-forming capacity of the 3 groups. In addition, no correlation was found between the number of colonies and the clinical stage within the patient group. T-cells from 8 of 21 patients and from only 1 of the healthy donors of control group II failed to respond. However, the frequency of nonresponder individuals in the 3 groups was not significantly different, as demonstrated by the analysis of the data by the chi-square test and Fisher's exact probability test.

The abundance of nonresponders in the CLL group



TEXT-FIGURE 1.—Colony formation by T-cells from B-cell CLL patients and control groups stimulated with PHA. Cells were plated at a concentration of 3×10^5/dish. Colonies were counted on day 6. Results are expressed as numbers of colonies/plate.

prompted further studies on the possible mechanisms of the unresponsiveness. T-cells from the 8 nonresponder patients failed to form colonies also when cultured with a wide range of mitogen concentrations or with media containing different proportions of AC CM. Furthermore, we observed no colonies even by culturing the cells for long periods (up to 12 days).

Colony formation was not detected in 3 CLL patients also when T_G, which are generally increased in CLL (*3*) and exert a suppressive effect on certain in vitro responses (*23, 24*), were removed from the T-cell suspensions. Moreover, we studied the presence or absence of suppressor cells by mixing the patients' T-cells with normal T-cells and by testing the mixture for colony formation. In three experiments with 3 different patients, the normal T-cells formed the expected number of colonies in the presence of CLL T-cells. The problem of whether or not the low proportion of the malignant B-cells contaminating the T-cells could exert a suppressive effect was also investigated. Peripheral blood cells from the patients were depleted of T-cells by rosetting with E_N, mixed with normal T-cells, and cultured.

Table 1 shows one representative experiment of three. Suppression of colony growth was not observed. Rather a threefold to fourfold enhancement of numbers of colonies was detected. This result is in agreement with that observed in different experimental systems (*25*).

Two of the nonresponder patients had CLL in stage 0; 1, in stage 1; 1, in stage 2; 1, in stage 3; 3, in stage 4; and 2, untreated. This finding seems to exclude a correlation between lack of response and clinical stage or treatment.

PWM Induction of Colony Formation by CLL T-Cells

Purified T-cells from 15 CLL patients and normal controls were cultured in agar in the presence of both PWM and MNC CM. Preliminary experiments showed that this CM was necessary for the induction of colony formation, whereas AC CM failed to support colony growth (*19*). Under these conditions PWM-stimulated T-lymphocytes formed colonies that displayed the same morphology and kinetics of appearance as those of PHA-stimulated T-lymphocytes described above. Since MNC CM contained a strong GM-CSA, the same specific tests already described for the PHA system had to be performed to rule out the possibility that the colonies detected were of myeloid origin.

The results of the experiments are reported in text-figure 2. Some nonresponders were detected in all of the groups, and no significant difference between the responses of the patients and the controls was found. Only 3 of 7 patients who responded to PWM also responded to PHA. Again, no correlation was found between the cloning efficiency of T-cells and the clinical stage of the disease in each patient.

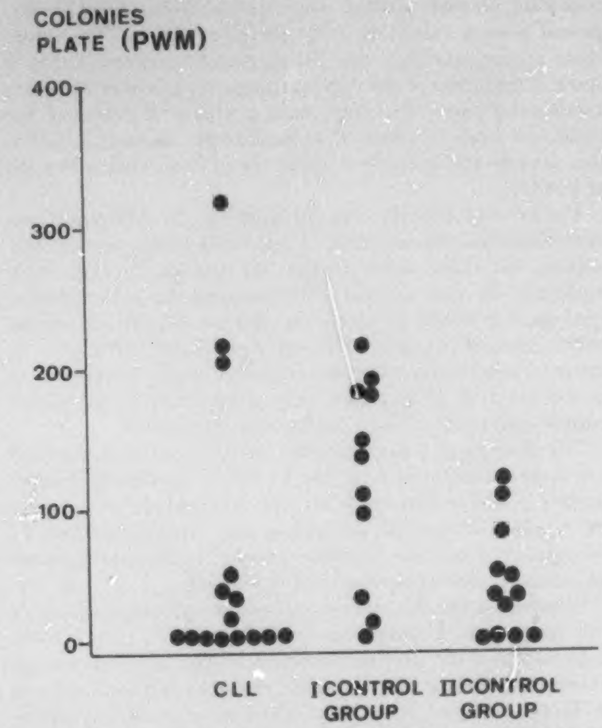
DISCUSSION

The present study demonstrates that T-cells from CLL patients display normal colony-forming capacity in agar. These results were obtained with an experimental system in which: 1) The responsiveness of highly purified T-cells from both patients and controls could be compared under identical conditions and 2) the influence of factors other than the "intrinsic" responsiveness of T-cells could be minimized or abolished.

TABLE 1.—*Influence of CLL B-cells on normal T-lymphocyte colony formation*[a]

Cell population	No. of colonies
Normal T-cells	400
Normal T-cells+CLL B-cells (3×10^4/plate)	650
Normal T-cells+CLL B-cells (6×10^4/plate)	850
Normal T-cells+CLL B-cells (9×10^4/plate)	1,100
CLL B-cells	0

[a] T-cells from a normal donor (3×10^5/plate) were cocultured with increasing amounts of B-cells from a CLL-patient (3×10^4, 6×10^4, and 9×10^4/plate) in the presence of PHA. CLL B-cells were cultured alone as a control. Colonies were counted on day 6. Results are expressed as numbers of colonies/plate.



TEXT-FIGURE 2.—Colony formation by T-cells from B-cell CLL patients and control groups stimulated with PWM. Cells were plated at a concentration of 3×10^5/dish. Colonies were counted on day 6. Results are expressed as numbers of colonies/plate.

The use of purified T-cells instead of unfractionated MNC overcame the difficulties represented by the presence of many malignant cells diluting out the T-cells in the CLL cell suspensions. Furthermore, the accessory cells needed for the induction of colonies could be substituted by the appropriate CM. Control experiments excluded the possibility that the observed colonies were formed by myeloid or erythroid precursors contaminating the T-cells. T-cells were induced to form colonies by PWM only in the presence of PWM-stimulated MNC CM. This special requirement is explained by the results of recent experiments demonstrating that, in addition to monocyte-derived factors, factors released by another nonadherent non-T accessory cell are needed for PWM-induced colony formation (*19*). PWM, together with these factors, activates a cell population, which, although overlapping, is not identical with that stimulated by PHA. This observation might also account for the differences in the response to PHA and PWM in each individual.

The statistical analysis of the data did not demonstrate any difference between the responses of the patients and those of the controls. These data and the results of previous experiments with liquid culture systems (*4, 7, 26–29*) would indicate normal proliferative and clonogenic capacities of T-cells from most CLL patients. In all of these studies the responses of each patient and control were generally dispersed over a relatively wide range of values. Therefore, these techniques may not be adequate to reveal either a small diminution of the response in each patient or to detect small subgroups of unresponsive patients. Because of the relatively high number of nonresponder normal subjects, this may be particularly true for the systems that make use of PWM.

Unlike that reported by others (*30*), no difference was noted between the responses of aged and young people. The reasons for these discrepancies are not easily explained, especially in view of the differences in the experimental systems, but could be traced to the use of unfractionated MNC, instead of purified T-cells. Age-related differences in the in vitro mitogen responses, therefore, might be connected to the function of accessory cells rather than to the proliferative capacities of the lymphocytes themselves.

The finding of a high number of CLL patients who did not form colonies in response to PHA warranted further studies. These studies ruled out the involvement of suppressor T-cells (*31*) and the possibility that insufficient doses of mitogen or of medium supplements were used and suggested an intrinsic unresponsiveness of the T-cells.

Whether or not this unresponsiveness represents a distinctive feature of a subgroup of CLL patients is presently unknown and the problem is being investigated further on a larger number of CLL patients. However, intrinsic defects of T-cell functions have been detected in certain lymphoproliferative disorders with the use of various experimental systems (*2, 3, 6*). In some cases the explanation for such defects could reside in the circulating T-cells' being part of the same malignant clone as that of the B-cells (*32, 33*).

Causes of Death and Sex Differences in Survival Times of Pigs With Untreated Hereditary Lymphosarcoma (Leukemia)[1,2,3]

H. S. McTaggart,[4] **P. Imlah,**[4] *and* **K. W. Head**[4,5]

ABSTRACT—The survival times from birth of 39 entire male Large White pigs with hereditary lymphosarcoma (L/S) were significantly shorter than those of 76 affected females. The survival times of 19 male castrates were for the most part intermediate between those for entire males and females. Analysis of the cause of death revealed that pigs with L/S (L/S-P) were more likely than pigs without L/S to die from colibacillosis, but this disease showed no sex predisposition. In uncomplicated deaths from L/S, weights of splanchnic lymph nodes, spleen, and thymus were greatest in females. The cell-mediated and humoral antibody responses of L/S-P were significantly poorer against 2,4-dinitrofluorobenzene (DNFB) and sheep red blood cells, poorer against skin homografts, but better against bovine serum albumin than those of healthy littermates. Healthy females had stronger DNFB reactions than did healthy males or castrates. Castrated L/S-P responded to DNFB better than did females and significantly better than did entire males.—JNCI 1982; 68:239–246.

Hereditary L/S of pigs is an autosomal recessive condition (*1*) that manifests itself during the first few weeks or months of the animal's life by the development of solid lymphoid tumors, especially in the splanchnic lymph nodes, and is accompanied by a lymphoblastic leukemia (*2*). In no observed case of L/S have these leukemia cells shown surface markers characteristic of either T-cells or B-cells.

In terms of morbid anatomy and histopathology, affected animals constitute a homogeneous group (apart from the increasing involvement of various organs with age) distinct from the various sporadic forms of L/S. The epididymis and testes of affected males, though usually macroscopically normal, are frequently found by histologic examination to have been invaded by the tumor as early as 100 days after the animal's birth. Conversely, the ovary and uterus have never been found to be affected, even in the oldest female examined (437 days).

In the ALL of childhood, the prognosis for boys is poorer than for girls (*3*). Testicular relapse is a special hazard in boys, although its role as either a cause of poorer prognosis or as an indicator of multiple organ involvement is still debatable (*4*, *5*). Because of the testicular invasion we observed in our pigs, we instituted a retrospective study of untreated cases of L/S to ascertain whether there was any difference in survival times of males and females and what effects, if any, resulted from early castration of males.

MATERIALS AND METHODS

Pigs.—L/S cases in this survey consisted of 134 animals (76 F, 39 M, 19 C) from 74 litters sired by 12 boars and out of 36 sows in the herd of Large White pigs described by Head et al. (*2*). All pigs were bred, reared, and kept under the same "minimal disease" conditions, though accidental breakdowns occasionally occurred. There was no intentional segregation of the sexes.

Of these animals, 100 (53 F, 28 M, and all 19 C) were allowed to live out their lives without antineoplastic treatment and either died of natural causes or were killed for humane reasons in the terminal stage of disease. The remaining 34 pigs were randomly selected for antineoplastic treatment or were killed to provide experimental material. At the commencement of such treatment or on being killed, they were classified as "withdrawn" in accordance with the requirements of the log rank test (*see* below). As each animal was withdrawn, the number of animals at risk in the overall survival analysis (text-fig. 1) was reduced by one, but the removal was not counted as an event within the meaning of the test. The cause of death of the withdrawn animals was classified as "miscellaneous." Confirmation of L/S in all the animals was made by necropsy and subsequent histopathology.

In earlier years, castration was performed routinely on males before 3 weeks of age, i.e. at an earlier age than that of any pig in which hereditary L/S has ever been detected. Castration had no demonstrable effect on the death rate. Males were left entire only if a working boar would be needed in about 12 months, in which case no male of the selected litter was castrated. In later years all males were left entire.

Survival curves based on age at death were constructed

ABBREVIATIONS USED: ALL=acute lymphoblastic leukemia; BSA=bovine serum albumin; C=castrated male(s); df=degrees of freedom; DNFB=2,4-dinitrofluorobenzene; F=female(s); LH=luteinizing hormone; L/S=lymphosarcoma; L/S-P=pig(s) with L/S; non-L/S-P=pig(s) without L/S; M=entire male(s); PBS=phosphate-buffered saline; PCV=postcapillary venule; PIA=porcine intestinal adenomatosis; SRBC=sheep red blood cells.

TEXT-FIGURE 1.—Survival curves based on age at death of pigs with untreated L/S. Females, ●—●; entire males, ■- - -■; castrated males, □—□; animals withdrawn from survival analysis (antineoplastic treatment had commenced or they were slaughtered for experimental reasons), /.

for the three sex categories and analyzed by the log rank (Mantel-Haenzel) test (*6*). All pigs that died in the piggery were examined by appropriate methods to establish the cause of death.

Diagnosis of death from colibacillosis was based on the postmortem condition of the gastrointestinal tract and confirmed if heavy growths of hemolytic *Escherichia coli* of known pathogenic serotypes could be cultured from the intestinal contents. Some cases of suspected colibacillosis were not serotyped because the pig had been dead too long before necropsy, it had been treated chemotherapeutically, or littermates dying from the same outbreak of the disease already had been serotyped. A litter was regarded as being at risk of death from colibacillosis if the death of any pig in that litter was attributable to a pathogenic strain.

The cell-mediated and humoral antibody responses of L/S-P were compared with those of their healthy littermates. All tests were performed in pigs at 3–4 months of age.

Immune response tests.—Cell-mediated response: *a*) Skin sensitivity reaction to DNFB. Skin sensitivity reaction to 10% DNFB was tested and scored as described in (*7*). The responses in 18 L/S-P (10 F, 5 M, 3 C) were compared with those in 38 healthy pigs (18 F, 14 M, 6 C). Up to 4 L/S-P came from each of 9 litters of L/S carrier × L/S carrier parentage. Of the healthy pigs, 8 were from 2 of those litters. The remaining 30 healthy pigs were from 4 litters of noncarrier × noncarrier parentage. *b*) Skin graft rejection. An exchange of full-thickness skin grafts of 6.26-cm^2 area was made between 6 L/S-P (2 F, 4 C) and 6 healthy littermates (2 F, 1 M, 3 C). Grafts were exchanged at a site approximately 5 cm below the dorsum behind the shoulder blade. Rejection time was assessed on total separation of the graft.

Humoral antibody response: *a*) Primary and secondary antibody response to SRBC. Two complete litters, one containing 2 L/S-P and 5 healthy pigs and the other containing 4 L/S-P and 4 healthy pigs, were given two 10-ml sc injections, 4 weeks apart, of a 30% suspension of washed SRBC in PBS, (pH 7.2) from a type O sheep. Serum samples were taken before immunization and on the 10th day after each injection. Type O SRBC were used as the source of antigen and as the test cell to avoid the possibility of reaction with the natural blood group antiserum anti-A, in the serum of blood group O, and "−" (i.e., A − ve, O − ve) pigs. All sera were subjected to a hemolytic test after heat inactivation at 56°C for 0.5 hour, with neat rabbit sera absorbed with type R SRBC as the source of complement. The test was set up in 7-mm disposable tubes with sera titered in doubling dilutions. Test serum (5 μl) was mixed with 5 μl of a 1.5% suspension of washed (four times) SRBC in PBS. After 10 minutes, 5 μl of absorbed neat rabbit complement was added to each tube. The tubes were incubated at 20°C and shaken for 1 minute at the end of each hour, for a total period of 6 hours. At the end of that time, a hemolytic reaction score ranging from 0 to 5 was made at each dilution. Due to antispecies reaction, an additive score was calculated for the preimmune sera, and this score was deducted from the additive score calculated for the primary and secondary test sera reactions. The remaining score was taken as the measure of the humoral antibody response.

b) Primary and secondary antibody response to BSA: Two complete litters, one containing 1 L/S-P and 11 healthy pigs and the other containing 1 L/S-P and 6 healthy pigs, were given two 5-ml sc injections, 4 weeks apart, of a 5% mixture of BSA in PBS (pH 7.2). Preimmune, primary, and secondary response serum samples were taken 10 days after each injection. The tanned red cell (*8*) was used as a test system. Type O SRBC were formalized by the suspension of 25 ml of packed, washed (five times) cells in 200 ml of PBS, to which 50 ml of 40% Formalin in a dialysis tube was added. The tube was agitated for 3 hours and then punctured and removed. The mixture was left overnight at room temperature. Cells were then filtered through muslin, washed five times in PBS, and kept at 4°C in 100 ml PBS. For tanning, 10 ml of formalized cells (≈25% concentration) was suspended in 90 ml of 0.01% tannic acid and incubated for 15 minutes at 37°C in a water bath. Cells were then washed three times with PBS and made into a final 1% suspension with PBS. The cells were coated with BSA. (An equal volume of 1% tanned cells was mixed with an equal volume of 1% BSA in PBS and incubated for 1 hour at 37°C.) The cells were then washed five times in PBS and made into a 1.5% suspension in PBS containing 1% normal rabbit serum that had previously been heat inactivated at 56°C for 0.5 hour and absorbed with uncoated tanned SRBC to remove nonspecific agglutinins before being tested against coated cells. Tests were set up in microtiter plates with V-shaped wells. In each well, 5 µl of doubling dilutions of test sera was mixed with 5 µl of a 1.5% suspension of coated cells. Agglutination was read after the mixture had remained overnight at room temperature. An agglutination reaction ranging from 0 to 5 was scored for each well for preimmune, primary, and secondary test sera. No preimmunization reaction was observed.

RESULTS

Survival Curves

Text-figure 1 presents the overall survival curves, based on age at death, for three sex categories. The relative death rate (the ratio of observed to expected deaths) for females was 0.82; for entire males, 1.43; and for castrates, 1.20. The median survival time was 201 days for females and 131 days for entire males. The median survival time of castrates again was intermediate at 156 days. Although the log rank test indicates that the overall differences among the three survival curves were significant (X^2, 6.4; df, 2; $P<0.05$), the difference between entire males and castrates was not (X^2, 0.4; df, 1; $P>0.5$). When the data for males were combined, the difference in survival times of females and males (including C) was significant (X^2, 5.9; df, 1; $P<0.02$).

Sex Distribution of L/S Cases

In earlier publications (*1, 2*) we stated that we had observed no significant sex bias in the distribution of L/S cases. In the present survey, the observed number of females with L/S was only one less than the expected 25% for those of L/S carrier × L/S carrier parentage and old enough to be diagnosed (table 1). However, males (including C) were underrepresented, though the shortfall from expectation was not statistically significant (χ^2, 1.5; df, 1; $P>0.2$).

Usually, the number of male pigs born exceeds that of females by a few units of percentage, and the mortality of males is higher than that of females (*9–11*). These male-to-female ratios were reflected in the 75 litters of non-L/S carrier × non-L/S carrier parentage (non-L/S litters) in our piggery that were contemporaneous with the 74 litters of L/S carrier × L/S carrier parentage (L/S litters) from which the L/S cases were derived (table 1). Males accounted for 52.30% of the total number of pigs born in non-L/S litters but for only 50.37% in L/S litters. During the first 3 weeks of life, the death rate in non-L/S litters was 11.9% for females and 25.2% for males. In L/S litters the death rate was much higher for both sexes (F, 22.75%, M, 34.5%). At 3 weeks of age, males were fewer than females: 48.2% in non-L/S litters, 46.3% in L/S litters.

Causes of Death

All 134 pigs in this survey (table 2) showed L/S lesions at necropsy, which were confirmed by histopathology. The postmortem data for the 100 untreated pigs were similar to those recorded in more detail for the series of 53 in our previous paper (*2*). As noted in that paper, some pigs also exhibited lesions of intercurrent disease. Where the lesions were similar to those found in non-L/S-P that had died, we assumed that the L/S-P had died or were dying from intercurrent disease. When no lesions of lethal intercurrent disease were present, we classified the cause of death as L/S.

Colibacillosis.—L/S-P that died from colibacillosis were between 25 and 108 days old. By that time non-L/S littermates also had died from similar symptoms and had the current pathogenic *E. coli* serotype. The colonization and adhesion of enterotoxigenic *E. coli* in the intestine, and the animal's subsequent development of disease with eventual death or recovery, have a complex etiology (*12, 13*). Because of the complicated interaction of managemental factors, microbiologic considerations, and the inherent reactivity of the host pig, we could not be certain, even in a single litter, that all pigs were equally at risk. Nevertheless, we considered the possibility that L/S pigs were more susceptible to coli-

[a] Peritonitis due to perforation of an ulcer of the gastrointestinal tract.

[b] β-Hemolytic group L streptococcal infection.

[c] L/S-P that died after antineoplastic treatment or were killed to provide experimental material. Data for these animals were removed from survival analyses, and the animals were classified as "withdrawn." The ages indicated are ages at withdrawal and not at death.

[d] *H. parainfluenzae suis* infection.

[e] *S. dublin* infection.

bacillosis than non-L/S pigs worthy of examination (*see* later).

PIA.—The outbreak of a hemorrhagic bowel syndrome associated with intestinal adenomatosis, described by Rowland and Rowntree (*14*), occurred in the same minimal-disease, hysterectomy-derived herd in which the L/S cases occurred. In the period covered in this paper, only a few deaths occurred in L/S-P and non-L/S-P in which PIA lesions were found and the presence of *Campylobacter sputorum mucosalis* was demonstrated by the method of Lawson and Rowland (*15*). The etiology of PIA seems to be even more complex than that of colibacillosis, and any relationship to coexisting L/S is even more debatable.

Perforated ulcer.—A perforating ulcer of the gastrointestinal tract, with subsequent peritonitis and death, was found in the colon of a 60-day-old male, the duodenum of a 67-day-old female, the jejunum of a 205-day-old female, and the fundus of the stomach of a 437-day-old female. Similar deaths were recorded in non-L/S-P but with much less frequency. Although the gut might be diffusely involved with the tumor, ulceration was not in an area of gut particularly severely affected; i.e., ulceration did not occur in a localized L/S. Many factors may interact to devitalize the gut and allow ulceration to occur. Among these are the diffuse involvement of the lymphoid tissue of the gastrointestinal tract, which displaces normal tissues; the possible interference with immune defense; the weight of the gastric-mesenteric lymph node mass hanging on the mesentery; and the erratic feeding associated with the animal's depression in the late anemic and emaciation stages of the disease.

Haemophilus *serositis.*—New pathogens introduced into a minimal disease herd tend to cause an explosive disease outbreak, as happened with *Haemophilus*. In 1 month before the outbreak was controlled by therapy and management, of 12 sows and gilts, 3 non-L/S-P (455, 897, and 1,152 days old) and 1 L/S-P (304 days old) died of pneumonia, pleurisy, and pericarditis. *H. parainfluenza suis* was recovered in all cases. Of the other sows, 4 became ill but recovered. The disease affected the whole piggery and despite treatment, 2 piglets (13 days old), a male and a castrated non-L/S-P (120 and 102 days old), and 2 castrated L/S-P pigs (79 and 99 days old) died. That a pig had L/S did not apparently influence the morbidity or mortality.

Salmonellosis.—A similar accidental break in the minimal disease status of the piggery was caused by a *Salmonella* infection. At the time of the occurrence the cattle in a nearby barn were affected with salmonellosis (*16*). The drainage from a part of the piggery is to a common drain with that of the cow barn. This drain became blocked, the piggery was flooded and 2 L/S-P died of salmonellosis during the resultant outbreak. One was a 243-day-old female that had an extensive necrotizing bronchopneumonia from which *S. dublin* and *Corynebacterium pyogenes* were recovered. The other, a 249-day-old castrate, died as a result of a fibrino-necrotic enteritis from which *S. dublin* was recovered. A 2-cm spherical nodule present at the castration site on one side proved to be a remnant of epididymis infiltrated by L/S tissue.

Streptococcal infections.—Within 6 days, 2 gilts with L/S died, and β-hemolytic group L streptococci were recovered. In a 227-day-old animal, the recovery was made from aortic valve endocarditis lesions, kidney abscesses, and polyarthritis of all major limb joints. Identification of infection also was made from the culture of joint tissue from a 359-day-old sow that exhibited such severe polyarthritis that she was destroyed for humane reasons. Much of the last week of her life was spent lying on her left side, and at necropsy the left cardiac lobe of the lung showed a purulent pneumonia from which *C. pyogenes* was recovered.

Pneumonia.—Despite the occasional accidental breakdown of minimal disease conditions in the piggery, enzootic pneumonia never was present. A very small, ill-thriven male L/

S-P (86 days old) died after being moribund for several days, and at necropsy he showed an extensive necrotizing pneumonia from which *C. pyogenes* was recovered. Another very small, ill-thriven female L/S-P (83 days old) died, despite antibiotic therapy, after 3 days of dyspnea. Necropsy revealed marked pleural effusion and an interstitial pneumonia, but only *E. coli* could be recovered on examination of the cultured tissues.

Trauma.—A 70-day-old female L/S-P was savaged by her littermates and died as a result of a fractured rib that lacerated the lung and caused hemothorax. This type of lesion had not been seen in non-L/S-P of that age, though fighting in the piggery sometimes breaks out. The lesion may have occurred because the L/S-P was so much smaller than her penmates. A 361-day-old female L/S-P was destroyed because she could not rise after she slipped and fell. Necropsy revealed severe tearing of the muscles of the hindlimb. Heavy sows that did not have L/S have damaged themselves in falls, but this gilt with L/S, though not emaciated, could not be classed as overweight. The fall may have occurred because of the weakness sometimes observed in advanced cases of L/S.

Tumor.—In addition to involvement of the lymphoid tissues of lymph nodes and spleen, we found tumor replacement of bone marrow with resultant anemia and thrombocytopenia. The lymphoid tissue of the gastrointestinal tract was always involved in a diffuse manner, and the liver became progressively infiltrated; interference with digestion, absorption, and metabolism could therefore be expected. In a disease in which so many organ systems are involved, difficulty is often encountered in deciding which site of maximum dysfunction is responsible for the death of the pig.

Effect of Sex on Risk of Death from Various Causes in L/S-P

When the data for all 134 pigs were examined together, the survival time of males was significantly shorter than that of the females. Table 2 shows that the two untreated categories with the largest number of deaths were colibacillosis and tumor. We decided to analyze these groups to determine whether sex differences in survival were associated with a particular category.

Death from colibacillosis.—As seen in table 2, all of the animals with colibacillosis had died by age 124 days. In the present survey, 65 L/S pigs were at risk of death from colibacillosis. Table 3 indicates no significant difference among the three sex categories (χ^2, 2.7; df, 2; $P>0.2$) in the number of deaths from the disease. Thus, although text-figure 1 shows a more precipitous fall in male and castrate than in female survival curves before 100 days, the fall was not due to increased susceptibility to colibacillosis, which is the most common cause of death in this age group (*see* table 2). The difference in survival curves is due to the fact that male deaths from colibacillosis were spread over a narrower age range (30–61 days) than that of castrates (28–78 days) or that of females (25–74 days). Moreover, no obvious differences were present in the histopathologic findings for the sexes in this group of L/S-P—only minor differences in organ weights.

TABLE 3.—*Causes of death of L/S-P in litters at risk of colibacillosis: Present survey*

Cause of death	F	C	M	Total no.
Colibacillosis	17	7	15	39
Other causes	15	6	5	26
Total No. at risk	32	13	20	65

Before the present survey was undertaken, an earlier study (McTaggart HS, Imlah P, Head KW: Unpublished data) had been made of the effects of colibacillosis. It involved 207 pigs in 27 litters of L/S carrier × L/S carrier parentage, in which L/S occurred or was expected and in which L/S-P were also at risk of death from colibacillosis. Table 4 shows that of these pigs, 61.5% (but only 16.7% of non-L/S-P) died of colibacillosis. The difference is very highly significant (χ^2, 33.9; df, 1; $P\ll0.001$). Use of the chi-square test was not fully justified because there could conceivably be a litter effect on mortality from colibacillosis (although such an effect was not obvious from the data), and the independence assumption of the test would not be satisfied. Nevertheless, the magnitude of such an effect could not be large enough to affect the conclusion of an association between L/S and death from colibacillosis. However, no significant difference in susceptibility to death from colibacillosis was apparent among the three sex categories in either L/S-P (χ^2, 2.0; df, 2; $P>0.1$) or non-L/S-P (χ^2, 1.7; df, 2; $P>0.1$).

Death from tumors.—As seen in table 2, only 3 (2 F, 1 M) of the 41 animals in this category died before they were 125 days old. Although the figures suggest that females survive longer than castrates and that both survive longer than entire males, when the data were subdivided into sex and age subsets the numbers were too small in some groups for meaningful statistical analysis.

We concluded that although there is a significant difference between the overall survival of males and females, our data do not warrant our attributing the difference to any particular cause or causes of death.

Lymph Node and Organ Weights of L/S-P That Died from Colibacillosis

Because L/S cases progress clinically at different speeds, we decided to test the hypothesis that there might be a critical lymph node weight at which pigs die and that males reach this weight before females. Analyses were made of absolute weights and relative weights (g/kg body wt). Inasmuch as the conclusions from both sets of data were the same, only absolute weights were considered.

TABLE 4.—*Causes of death in L/S carrier × L/S carrier litters at risk of colibacillosis: Study prior to present survey*

Group	Cause of death	F	C	M	Total
L/S-P	Colibacillosis	11	4	9	24
	Other causes	7	5	3	15
Non-L/S-P	Colibacillosis	10	13	5	28
	Other causes[a]	65	47	28	140
Total No. at risk		93	69	45	207

[a] Including pigs commercially slaughtered.

Increases in L/S lymph node weights occur with age (row 1, tables 5, 6). Thus in comparisons of lymph node weights of pigs of similar ages that died from similar causes, the variable was their sex. When the data for the three sex categories were compared, Duncan's new multiple-range test was used to determine significant differences. When the data for males and castrates were combined because of small numbers, Student's *t*-test was used.

Rows 1–3, table 5, present the data for 30 L/S-P, of a narrow age range, that died from colibacillosis. Data for lymph nodes are given in order of decreasing weight, and the order is the same for each sex. The mesenteric lymph node, gastric lymph node, spleen, and thymus weights of females were greater than those of males and castrates, but none of the differences among the groups were significant.

In rows 4–9, table 5, the data were separated into three categories according to body weight. Because the lymph node and organ weights for males and castrates were similar in rows 1 and 2, the data were grouped together. The order of lymph node weights remained the same as in rows 1–3, but as the body weight increased so did the lymph node and organ weights. The greater thymus and spleen weights in row 3 mainly reflect the weights in the heaviest female category (row 9). The mesenteric and gastric lymph node weights were greater for females than for males (including C) in each body weight category, but the differences among the sex groups were not significant. In the heaviest body weight category, the female thymus was significantly heavier than that of the males plus castrates (*t*-test, 4.2; df, 4; $P<0.02$).

Because healthy pigs were not killed at age 44–79 days, data for non-L/S-P that died of colibacillosis (rows 10–15, table 5) were used for comparison with data for the L/S-P. Weight categories were the same as for the L/S-P. Comparison of the data in row 10 with those in row 11, 12 with 13, and 14 with 15, shows no obvious sex differences in non-L/S-P. In non-L/S-P, the smaller the body weight the smaller the thymus was, indicating that thymus involution is greatest in poorly nourished pigs even when no L/S was present. All lymph nodes were enlarged in the L/S pigs, as compared

to those in non-L/S-P, with enlargement greatest for the gastric nodes, then the mesenteric nodes, and least for the prescapular nodes.

Lymph Node and Organ Weights of Older Pigs

Rows 1–3 (table 6) present data by sex on causes of death in L/S-P at ages 110–209 days. The order of the lymph node weights remained essentially the same as those for the younger L/S-P (table 5), but no significant sex differences in lymph node or organ weights were apparent. Rows 4 and 5 show weights for healthy pigs slaughtered at the abattoir for meat or killed to supply experimental material. In a comparison of rows 4 and 5 with rows 1–3, the most noticeable feature was the marked involution of the thymus in the L/S-P and the marked increase in their spleen weights. The order of lymph node enlargement in L/S-P was similar to that seen in the younger pigs (table 5).

Rows 6 and 7 (table 6) give the data for L/S-P that were more than 290 days old, at which time the entire males had died. (There was no control group for this weight category.) Three interesting developments were noted: The older L/S-P had more thymus than did the younger L/S-P (rows 1–3); the spleen enlargement was massive due to a mixture of tumor and extramedullary hemopoiesis; and although the lymph node weights had become massive, the order of lymph node enlargement was maintained.

We concluded that no simple difference in lymph node involvement from L/S accounted for the difference in survival between the sexes.

Immunologic Responsiveness

The cell-mediated responses of L/S-P and healthy pigs, as measured by skin reaction to 10% DNFB and skin graft rejection time, are shown in table 7. The mean DNFB skin reaction score for healthy pigs was very significantly greater than that for L/S-P (*t*-test, 6.6; df, 54; $P<0.001$). For healthy females the mean reaction to DNFB was significantly greater than that for males (*t*-test, 2.6; df, 30; $P<0.02$). The mean reaction scores for castrates were intermediate and were not significantly different from those for females or those for males ($P>0.3$ in both cases).

The mean response for healthy pigs of L/S carrier × L/S carrier parentage was almost identical to the response for pigs of non-L/S carrier × non-L/S carrier parentage. We cannot conceive that the difference between L/S-P and healthy pigs could be due to litter effects, and we have been unable to demonstrate any strong litter effects in the sex differences.

In L/S-P the mean DNFB reactions for females and males were not significantly different (*t*-test, 1.3; df, 13; $P>0.2$). The mean reaction for castrates was greater than that of either but was significantly different only from the mean reaction for males (*t*-test, 4.9; df, 6; $P<0.01$). The mean skin graft rejection time for L/S-P was 4 days longer than that for healthy littermates; the difference was very highly significant (*t*-test, 6.9; df, 5; $P<0.001$). Insufficiency of numbers of animals prevented any comparison by sex.

The humoral antibody response scores for reaction to SRBC and BSA are shown in table 8. For healthy pigs the mean accumulated scores for reaction to SRBC were the same for the primary and secondary responses. For L/S-P the mean primary and secondary responses to SRBC were not significantly different. The mean primary response for L/S-P was significantly weaker than that for healthy pigs (*t*-test, 3.7; df, 13; $P<0.01$). The mean secondary response was very significantly weaker for L/S-P than for healthy pigs (*t*-test, 6.5; df, 13; $P<0.001$).

The mean primary and secondary responses to BSA for healthy pigs were not significantly different (*t*-test, 0.9; df, 16; $P>0.3$). In L/S-P the mean secondary response was significantly stronger than the mean primary response (*t*-test, 14.0; df, 1; $P<0.05$), and both responses were very significantly greater than the corresponding responses for

DISCUSSION

Although we demonstrated that male L/S-P have a significantly shorter survival time than do females and that testicular involvement is common in entire males, any analogy with childhood ALL is only superficial. In the pig, the sex differences in survival are apparent in untreated animals, whereas in children they have become apparent only in recent years with the long follow-up of aggressively treated individuals [(*3*); Innes EM: Personal communication].

ALL can be classified according to at least four main cell types (*17*). Of these, the T-cell type (15% of ALL cases) has a poor prognosis with present conventional chemotherapy and is four times more common in boys than in girls (*17, 18*). Hereditary L/S of pigs is probably a homogeneous, non-B- non-T-cell entity but to which of the human ALL types it corresponds, if to any, is not clear. Even morphologically, the abnormal mononuclear cells seen in the blood of L/S-P are not quite like those in any human ALL (Innes EM: Personal communication); for one thing, the cells have more cytoplasm. Furthermore, whereas ALL is about one and one-half times more common in boys than in girls (*3*), we found that hereditary L/S occurred less frequently than the 25% expected in male pigs of L/S carrier × L/S carrier parentage.

The higher death rate for males in L/S litters during the first 3 weeks of life possibly may be associated with a proportion of L/S cases not diagnosed at necropsy and subsequent histopathology. Similarly, the unexpectedly low proportion of males born may have been associated with prenatal deaths due to L/S, but as yet we do not have the techniques to establish the validity of this hypothesis.

Comparison of liver, spleen, and some lymph node weights for L/S-P and non-L/S-P that died from colibacillosis shows that the weights are heavier for LS-P, but that the thymus weights of the 2 groups were not markedly different (table 5). The increased likelihood that L/S-P will die of colibacillosis, therefore, does not seem to be thymus-dependent. Indeed, the involution of the thymus seems to correlate with the body weight of the pig rather than with the cause of death. If the decrease in thymus weight was inversely proportional to the increase in lymph node weight, one would expect a smaller thymus than that actually observed in the older L/S-P. The longest surviving females and castrates with L/S, although six times as old as the pigs that died of colibacillosis, had thymuses of comparable weight (tables 5 and 6), which might be interpreted as indicating that the ability of an L/S-P to survive depends on the retention of a moderate amount of thymus. Certainly, these organ weight figures show that the longer a pig survives the greater the weight of tumor tissue it carries, and apparently death does not automatically intervene at any fixed tumor weight.

Male and castrate L/S pigs that died from colibacillosis between the ages of 44 and 74 days had lighter gastric lymph node, mesenteric lymph node, spleen, and thymus weights than did females of the same age that died of the same disease. The critical regulators of sexual maturation in healthy male pigs are the LH and testosterone plasma levels, which do not start to rise until approximately 80 days of age; these levels peak at about 110 and 138 days, respectively, and then return to a low level [Florcruz SV, Lapwood KR (*19*)]. In addition, those authors believe that body weight is important in the regulation of spermatogenesis, which they found occurred between 90 and 127 days. Separation of the data into three ascending weight categories for the 44- to 74-day-old pigs that died of colibacillosis revealed that the heavier weights of gastric and mesenteric lymph nodes occurred in the females in each category. However, spleen and thymus weights were greatest only in the heaviest females (table 5).

Sex differences in organ and lymph node weights are difficult to explain simply as an increase in tumor or as an increase in host defense cells. The differences occur before male puberty sex hormones arise in males—not when male puberty sex hormones peak and establish the adult pattern (at 110–209 days old; table 6)—and before estrus cycles are apparent in females. In the oldest age group (290–360 days old), in which no entire male L/S-P still were alive, the females had heavier gastric lymph nodes, mesenteric lymph nodes, and thymuses, but not spleens, than did castrates. Therefore, we believe that sex hormones at levels governing normal, functional sexual maturity are not responsible for the differences in survival and tumor progress, because even in older pigs normal spermatogenesis and normal ovarian cycling were not observed. The observation that cellular immune responses were reduced in L/S-P is compatible with the marked regression of the thymus in all cases. The significantly better sensitivity reactions to DNFB of castrates as opposed to those of male L/S-P (table 7) suggest a possible reason for the better survival rates for castrates. Unfortunately, only for the DNFB immune response test system were sufficient animals involved to permit a comparison between the sexes, and generalizations should not be made on the basis of one system.

The significantly better humoral antibody responses to SRBC of healthy pigs as compared to those of littermates with L/S could possibly give some indication as to why the L/S-P are more susceptible to *E. coli* infections (table 4). The immune systems probably are quite different. The SRBC reaction depends mainly on an IgM and IgG response, whereas in *E. coli* infections an IgA response is favored along with the adhesive "stick" gene for K88 antigen (*13*). This difference in the immune response of L/S-P has not been investigated.

The enhanced responses of the 2 L/S-P to BSA (table 8) are evidence that all immune mechanisms are not depressed by the disease. In these pigs, the immune mechanisms were improved. As reported previously (*20*), an increase occurs in the levels of IgM and IgG in the sera of L/S-P. The direct agglutination reaction against BSA-coated tanned cells may involve IgM in the primary and, to a certain extent, in the secondary response. To judge the entire immune responsiveness of L/S-P as being inferior to that of their healthy littermates, on the basis of observations made with the use of certain immune test systems, would be unwise. With regard to thymus-dependent systems, the responses of L/S-P are obviously inferior to those of their healthy littermates. The responses of L/S-P to certain other humoral antibody systems, involving complement fixation and reaction to particulate antigens, are also inferior but to other systems, involving soluble antigens, they are superior.

The observation that healthy female pigs had a better immune response to DNFB than did healthy male pigs is in general agreement with immune response studies in humans (*21*) and mice (*22*). Studies of thymus-dependent and thymus-independent responses of entire male, female, and castrated mice (*23*), demonstrated that the responses of female and castrated mice were superior to those of the entire males, but that the thymus-independent responses of castrated mice were superior to those of the females. In our study, the 3 castrated L/S-P pigs showed a better reaction to DNFB than did the male or female L/S-P. However, McFarlin and Balfour (*24*) demonstrated that skin contact sensitivity induced by DNFB is inhibited in thymectomized newborn pigs, which implies that the DNFB reaction is mainly thymus-dependent in the pig. In this respect castrated L/S-P appear to have some superiority in their degree of reaction. The superior immune response of castrated mice (*23*) was related to hyperplasia of the thymus and spleen, with an increase in the number of cortisone-sensitive cells in the thymus and an increase in the number of peripheral lymphocytes. Such differences have not been investigated in detail in pigs; however, as can be seen in table 6, healthy male pigs (16 of 19 were C) had heavier spleen and thymus weights than did comparable females. We have therefore demonstrated a reduction in the ability of male pigs to survive with L/S and that this reduction is not related to an increased susceptibility to some infections (e.g., colibacillosis) or to a more rapid growth of tumor mass in males than in females. In part, the difference in biologic behavior of untreated L/S-P of different sexes may be due to differences in their immune responsiveness. There are, however, fragments of evidence to suggest that the difference is mediated through the testes and epididymis. Batchelor and Chapman (*25*) concluded that a higher rate of antibody synthesis in female mice was not because of the presence of ovarian tissues, but rather that males were immunologically inferior due, in part, to the presence of the testes, although the immune system deficiency was not attributable to testosterone. Any effect of sex hormones in male L/S-P presumably must be at a time when those hormones are at a low level in the plasma, because tumor growth is not exacerbated with the normal occurrence of puberty. Moreover, the involvement of the epididymis remnant in an incompletely castrated pig that died from salmonellosis 228 days after castration showed that only traces of testes may reduce immunity. A castrated male fetus has a neutral or female sex pattern because the testes of the male superimposes "maleness" by stimulating wolffian duct growth by an androgen and by suppressing the müllerian duct by an unknown hormone (*26*). This phenotypic sex determination occurs in the womb when LH and testosterone levels are very low and may, in part, be mediated through the H-Y antigen, a product of the testes-determining Y-chromosome gene (*27*).

Castration of male mice results in the lymph node PCV endothelial cells becoming nearer in character to those of the female, presumably, because of their release from a direct depressive effect of androgens [Kittas L, Henry C (*28*)]. Those authors discuss the ways in which gonadectomy and estrogen administration may influence both thymus activity and PCV control of lymphocyte recirculation. The gonad would seem to be more important than the Y-chromosome in influencing immunologic responsiveness. Gonadectomy and administration of estrogen could have the type of moderating effect on the biologic behavior of L/S that we have outlined.

In summary, the expected life-span of a pig may be shortened by many factors. L/S invariably leads to the death of the pig at an early age. Moreover, an L/S-P may die from intercurrent disease sooner than from the tumor alone. Conversely, some factors appear to be present in the L/S-P that may slightly extend its life-span. We believe that there is a hierarchy of factors that influence the life-span: *a*) Intercurrent diseases acting alone that cause death at any age and are unrelated to the progress of the L/S (e.g., *Haemophilus* and *Salmonella* infections). The number of deaths in a group of L/S pigs due to such diseases will be governed by the number of pigs exposed to the causal agent. In a conventional piggery, more deaths would be expected in this category than occurred in our minimal disease herd. *b*) Intercurrent diseases that have a characteristic morbidity age distribution (e.g., colibacillosis). Mortality from such diseases is increased in pigs already affected with L/S. The number of deaths in a group of L/S-P due to intercurrent diseases will be governed by such factors as a new pathogenic strain of the disease organism, the herd immune status in respect to the current organism's serotype, and changes in feeding and management. *c*) The intrinsic growth rate of the L/S in a particular pig, with eventual death due to multiple organ system failure. *d*) Host pig factors that modify the rate of L/S growth to a limited extent (e.g., sex).

Calorie Restriction: Effect on Growth of Human Tumors Heterotransplanted in Nude Mice[1,2,3]

Beppino C. Giovanella,[4,5] **Randall C. Shepard,**[4] **John S. Stehlin,**[4] **John M. Venditti,**[6] *and* **Betty J. Abbott**[6,7]

ABSTRACT—The presence of 4 human malignant tumors (1 breast, 1 lung, and 2 colon carcinomas) growing subcutaneously as heterotransplants in nude mice did not significantly affect the body weights of adult animals until the tumors reached very large dimensions (tumor wt >15% of the body wt). However, a colon carcinoma (HT 29) induced a cessation of the natural rate of body weight increase when it grew in young adults (animals weighing ≈25 g which will gain 6 g or ≈25% body wt in 1 mo). Calorie restriction at all the levels tested (8, 6, 4, and 2 g/day/mouse) with standard pelletized mouse food produced both weight loss in the animals (with and without tumor) and a lowering of the growth rate of all the 4 tumors tested growing at a subcutaneous site and/or under the kidney capsule. Each tumor responded differently to the calorie restriction. The 4 tumors tested grew equally in both male and female nude mice. Young animals weighing 20 g inoculated with a fifth tumor (MeWo melanoma) exhibited tumor growth inhibition proportional to restriction of calorie intake. Their survival, however, did not improve.—JNCI 1982; 68:249–257.

The effect of calorie restriction on the incidence and growth rate of malignant tumors in animals has been the subject of many papers (*1–18*). However, much less is known about the effect of calorie restriction on the incidence and growth rate of malignant tumors in humans (*19*) because it is not possible to starve human cancer patients for evident ethical and practical reasons. Since the nude mouse (*20, 21*) is capable of accepting human tumor heterotransplants because of its immunologic deficiency (*22, 23, 24*), it is now possible to submit human tumors in the nude mouse host to calorie restriction under the same rigorous experimental conditions used for the study of animal tumors. We have studied the effects of different degrees of calorie restriction on the growth rate of 5 human malignant tumors (2 colon carcinomas, 1 breast carcinoma, 1 lung carcinoma, and 1 melanoma) serially transplanted into nude mice.

MATERIALS AND METHODS

Mice—Noninbred nude Swiss mice were bred and experimented on within the Cancer Research Laboratory, St. Joseph Hospital, under strictly pathogen-free conditions according to the procedures described by Giovanella and Stehlin (*25*). For the calorie restriction experiments, the mice were isolated singly in polycarbonate cages. The desired daily amount (2, 4, 6, 8 g) of sterile pelletized autoclavable mouse food (Wayne Lab Blox Sterilizable; Allied Mills, Inc., Chicago, Ill.) was introduced under sterile conditions into each cage. Such pelletized food contains 24% proteins, 4% fats, and 4.5% crude fiber. It is composed of corn and wheat flakes, soybean meal, wheat red dog, wheat middlings, fish meal, brewer's dried yeast, soybean oil, animal liver meal, vitamins, and minerals. One gram is equivalent to 3.7 calories. The controls fed ad libitum always had an excess of the same food present in the cages. We determined ad libitum food intake by feeding animals weighed amounts of powdered food placed at the bottom of a narrow-necked container. Under such conditions, the animal could eat as much as it wished, but spillage was minimized because to obtain food the mouse was forced to introduce its head and neck only and not its front paws into the opening. Every 24 hours, the container was withdrawn, the contents were weighed, and the amount eaten was established by the subtraction of the amount of food still present from the original amount introduced in the container. As an additional precaution, the small container was fixed at the center of a petri dish 10 cm in diameter. When eating, the mouse had to perch itself on the rim of the petri dish so that urine and feces fell outside the petri dish. This arrangement allowed us to collect (with a brush) and weigh even the smallest amounts of powdered food spilled by the mouse. All the animals received water ad libitum. To the water, sterilized by passage through a Millipore filter, was added 1 ml multivitamin infusion/liter (U.S. Vitamin and Pharmaceutical Corp., Tuckahoe, N.Y.) [*See* (*25*) for complete composition of the multivitamin infusion.] This diet was fully balanced, and the only restriction practiced was on the calorie intake.

BX #1 in the screening panel, Division of Cancer Treatment, NCI) is an invasive ductal cell carcinoma of the breast heterotransplanted in our laboratory from a primary tumor of a 29-year-old woman and serially carried for 48 passages in nude mice. This tumor has been extensively studied, especially for its response to experimental chemotherapy (*26–29*). Human lung carcinoma Doyle (DO #1; also LX #1 in the screening panel, Division of Cancer Treatment, NCI) is an undifferentiated epidermoid carcinoma of the lung heterotransplanted in our laboratory from a subcutaneous metastasis of a 48-year-old man and serially carried for 39 passages in nude mice; it has been extensively studied (*27, 28, 30*). Human colon carcinoma Squires (SQ #1), also extensively studied in our laboratory and other laboratories (*27*), is a moderately differentiated adenocarcinoma of the colon; it was heterotransplanted in our laboratory from an iliac lymph node metastasis of a 50-year-old man and serially carried for 16 passages in nude mice. Human colon carcinoma HT 29 (CX #1 in the screening panel, Division of Cancer Treatment, NCI) was received from the Mason Research Institute, Worcester, Mass., as a nude mouse tumor serially transplantable. It was obtained by the injection in nude mice of cells of the tissue-cultured line HT 29 (passage 100) received from Dr. Jørgen Fogh, Sloan-Kettering Institute, Rye, N.Y., who established it in culture from a primary mucinous adenocarcinoma of the colon in a 44-year-old woman (*31*). This tumor has been carried for 26 passages in nude mice and is also well studied (*29, 32*). The MeWo cell line was originated by Kodera and Bean from a malignant melanoma metastatic to a lymph node of a 74-year-old male in 1974. It has been well studied and characterized both in vitro and in vivo in nude mice (*33*). All of these tumors were transplanted in our laboratory either by the sc injection of 0.5 ml of the finely minced tumor suspended in EMEM (GIBCO, Grand Island, N.Y.) (10% wt/vol, equivalent to ≈50 mg wet wt tumor) or by the surgical insertion of a small fragment of the tumor under the kidney capsule according to the method of Bogden et al. (*29*).

TABLE 1.—*Food intake of nude and heterozygous Swiss mice, groups of 4 mice*

Mice	Age, mo[a]	Food intake[b]	
		g/mouse/day	mg/g/day
Nude	1	6.5±0.4	399
	3	8.1±0.7	245
Heterozygous	1	5.9±0.6	272
	3	5.5±0.2	166

[a] Average body weights at 1 mo of age were 16.3 g for the nude mice and 21.7 g for the heterozygous mice. Average weights at 3 mo of age were 33.1 g for the nude mice and 40.5 g for the heterozygous mice.

[b] Values are means ± SD.

Food intake and experimental procedures.—Groups of 50 nude mice fed ad libitum were inoculated with the same tumor. When the tumors reached the desired size, the animals were divided into groups of 10 (5 males and 5 females). From then on, each group received one of five food quantities: ad libitum, 8 g/mouse/day, 6 g/mouse/day, 4 g/mouse/day, and 2 g/mouse/day. The animals with subcutaneous tumors were individually weighed, and the tumor was measured every 2d day for at least 30 days after the start of treatment. The tumor weight in milligrams was calculated according to the formula $(ab^2)/2$, where a and b were expressed in millimeters. The subrenal capsule transplants were measured in situ at the moment of implantation by means of a micrometric ocular applied to a stereomicroscope and then by the same instrument when the mice were killed 11 days later.

The size of the tumor is given as average diameter, $(a + b)/2$, expressed in OMU (1 OMU = 0.1 mm). In most experiments, adult nude mice were used (i.e., animals whose weights do not increase any further or increase very slowly even if fed ad libitum). In some experiments, however, the effects of calorie restriction were compared in adult nude and young adult nude mice (i.e., animals that are in the last part of their normal weight gain period). Young adult mice will gain 25% body weight before they reach the adulthood plateau. The MeWo survival experiment was conducted with the use of groups of 8 animals that were inoculated sc with the tumor and fed ad libitum (6 g/day, 4 g/day, and 3 g/day) starting when the mice weighed 20 g. The animals were then followed until all the mice in a group died.

RESULTS

The results are summarized in tables 1–16 and in text-figures 1 and 2. No sex differences were observed. Accordingly, all the results are given as averages of groups composed of 50% males and 50% females. Table 1 shows the amounts of food consumed by young and adult mice when

fed ad libitum. Nude mice consumed more food than did their heterozygous furry littermates. Also, for adult nude mice, feeding 8 g/day/mouse is almost equivalent to ad libitum feeding. Table 2 shows that tumor-free adult nude mice (≈90 days old) if fed ad libitum very slowly increased their body weights. Such increase, although slow, was significant so that a male 1-year-old Swiss nude mouse in our colony not infrequently reached a body weight of 45–50 g. If calorie restriction was instituted, the body weight dropped initially and then rebounded if the calorie restriction was minimal (8 g/mouse/day) or leveled off at different levels if the calorie restriction was more severe. This phenomenon is explained in table 3, which shows the level of food intake (in mg/g body wt) with different diets and the leveling off of food intake after 3 days when the body weight stabilized. Table 2 shows that animals fed at 2 and 4 g/mouse/day, after initially losing some weight, leveled off at the same body weight, although the 2-g animals had a food intake that was one-half that of the 4-g mice (table 3). However, a profound difference existed between these two levels of calorie intake. Mice fed 4 g/mouse/day can live indefinitely, whereas mice fed 2 g/mouse/day will all die within 30–40 days. Thus for nude Swiss mice, the minimum food intake is about 200 mg/g/day, which will maintain them indefinitely at a lean 20- to 21-g body weight. If the diet was instated at a younger age when the animal was still growing and not just slowly fattening, the same basic observations were made (tables 4, 5). If the animals were provided with more than 200 mg food/g/day, they kept growing. Comparisons at the level of 2 g/mouse/day were not possible because the adults under these conditions had available only 100 mg food/g/day versus 150 mg for the young animals.

With ad libitum feeding, the growth of all 4 tumors depressed the body weights of nude mice. The depression was greatest with DO #1 lung carcinoma, a very invasive tumor. HT 29 colon carcinoma mildly depressed the weights of adult animals, but it totally suppressed the growth of young animals (table 6).

Calorie restriction reduced the growth of all 4 subcuta-

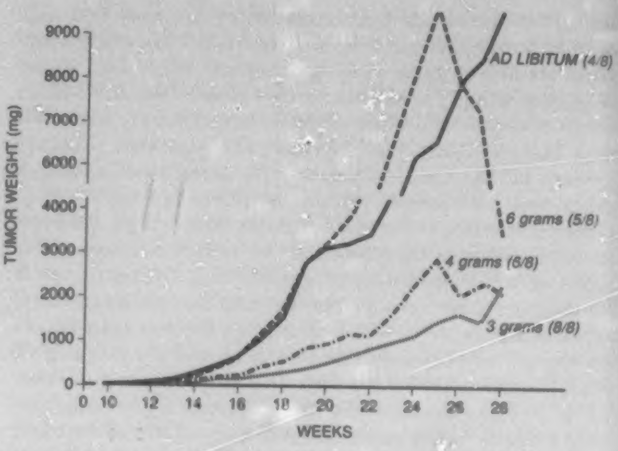
[a] Values are means ± SD. *Numbers in parentheses* are numbers of animals. *Numbers with plus signs in brackets*=weight gain, g.
[b] $P<0.01$ vs. day 0 data.

TABLE 6.—*Body weights of animals fed ad libitum*

Parameter[a]	Body weight, g[b]	
	HT 29 colon cancer, adults	
	Day 12	Day 40
No tumor	37.7	35.9 (+0.2) [+0.6]
Tumor	34.6	31.3 (−3.3) [−9.5] {−10.1}
	HT 29 colon cancer, young animals	
	Day 3	Day 38
No tumor	23.9	33.4 (+9.5) [+39.7]
Tumor	24.2	24.3 (−0.1) [−0.4] {−40.1}
	CL #1 breast cancer, adults	
	Day 10	Day 38
No tumor	34.1	36.5 (+2.4) [+7.0]
Tumor	33.8	31.6 (−2.2) [−6.5] {−13.5}
	SQ #1 colon cancer, adults	
	Day 13	Day 41
No tumor	33.6	35.3 (+1.7) [+5.0]
Tumor	33.7	33.3 (−0.4) [−1.2] {−6.2}
	DO #1 lung cancer, adults	
	Day 5	Day 33
No tumor	33.3	33.9 (+0.6) [+2.0]
Tumor	35.4	29.2 (−6.2) [−17.4] {−19.4}

[a] No tumor refers to control animals bearing no tumors. Tumor refers to experimental animals bearing tumors. In this and in all the following tables, the host weight of a tumor-bearing animal is obtained by subtraction of the tumor weight from the total weight.

[b] Days listed are days after tumor inoculation. *Numbers in parentheses* are body weight gains (+) or losses (−), in grams, after 28 days. *Numbers in brackets* are percent body weight gains (+) or losses (−) after 28 days. *Numbers in braces* are percent body weight losses (−) after 28 days of tumor-bearing animals relative to the weights of their non-tumor-bearing controls.



TEXT-FIGURE 2.—Tumor growth in same animals as in text-fig. 1. *Numbers in parentheses* at the end of each curve indicate No. of survivors at the end of the experiment/total No. of mice in the experiment.

noma inoculated sc into young nude mice weighing 20 g. Immediately after tumor inoculation, the mice were divided into 4 groups of 8 animals each and fed various levels of food (ad libitum or 6, 4, and 3 g/mouse/day). The body weights of the animals and the tumor growth curves are shown in text-figures 1 and 2. The number of deaths among the tumor-bearing animals are also indicated. The experiment was terminated after 28 weeks when all the mice in the 3-g group were dead. At that time, there were still 2, 3, and 4 survivors, respectively, in the 4-g, 6-g, and ad libitum groups.

DISCUSSION

The data obtained show that calorie restriction inhibited the growth of human tumors heterotransplanted at subcutaneous sites or under the kidney capsule in nude mice. Such inhibition of growth was both dose-dependent and tumor-dependent. For a given tumor, the more severe the calorie restriction, the larger the tumor growth inhibition. However, the same calorie restriction applied to different tumors caused different degrees of inhibitions of growth. These results parallel quite closely the results obtained by Tannenbaum and Silverstone (*17*) using animal tumors. Our data and those of Tannenbaum and Silverstone showed that tumor growth inhibition and host weight loss were closely correlated. The 4 tumors studied did not significantly affect the weights of the adult hosts until these tumors had reached very large dimensions. When 1 of these tumors was transplanted into young mice still increasing their body mass, the body weight gain was completely stifled. This inhibition of

body weight gain occurred even with a small tumor mass. Clearly, different tumors interfere in different ways with the host's metabolism. Substances secreted by the tumor probably play a major role in effects not directly attributable to the mechanical action of the tumor mass (such as increase in body weight and compression of vital organs). That human tumors can secrete toxic substances is well known (*34*). We also know that human tumors heterotransplanted into nude mice can and do secrete various products (such as hormones and unidentified proteins) (*35*). Some such products have already been identified as being toxic for the host mice (*36, 37*), and some have already been held responsible for weight loss among nude mice after heterotransplantation of certain human tumors (*38*).

Our findings should caution everybody engaged in experimental therapy studies involving human tumors heterotransplanted into nude mice about the need to keep a close watch on the weights of the treated animals throughout the experiment. Even short-term experiments are not exempt from such a caveat, as clearly shown by the kidney capsule experiments. Simple calorie restriction induced up to 62% tumor growth inhibition in the kidney experiments and 93% in the subcutaneous experiments. Fortunately, such inhibitions correlate closely with body weight loss, which can be easily monitored. Such losses must be minimized if reliable results are desired. For the achievement of such a goal, the first necessary precaution is the use of nude mice in good health. Nude mice affected by murine viral hepatitis and other infectious diseases lose weight rapidly (*39, 40*) due to both their reduced food intake and the extensive destruction of the liver, in the case of hepatitis. Such animals have no place in experimental therapy experiments, as we have already stated (*30*). Second, but no less important, is the monitoring of the debilitating effect of the antitumor treatment itself on the mice, as measured by weight loss. Our data indicate that any weight loss above 20% renders unreliable the results obtained. Also, our results clearly show the need for further studies on the role of calorie intake in cancer growth. It has already been demonstrated in animals that hyperalimentation stimulates considerably the growth of transplantable tumors (*41*). Nobody would deny the need to nutritionally support an emaciated cancer patient undergoing strenuous chemotherapy. Also, our own preliminary survival experiment shows that calorie restriction, although capable of limiting tumor growth, does not prolong and, if anything, shortens the life-span of the host. However, in view of our findings and those of others, it would not seem unreasonable to suggest a low calorie intake to cancer-free patients at high risk of tumor recurrence. Further studies are in process, with the use of the nude mouse model, on the incidence of takes of human tumors inoculated at minimum effective inoculum doses in animals fed at various calorie

Resting State Depth and Saturation Density as Modulated by Tumor Promoters and Culture Conditions: Relationship to Chemical Transformation in C3H/10T½ Cells [1,2]

David Miska [3] *and* **H. Bruce Bosmann** [4,5]

ABSTRACT—With the use of cultures of C3H/10T½ fibroblasts, the relationships of saturation density and cell resting state (G_0) depth to oncogenic transformation by 3-methylcholanthrene (MCA) were investigated. The tumor promoter 12-*O*-tetradecanoylphorbol 13-acetate (TPA), caused a small increase in the saturation density, but saccharin (SAC), a suspected promoter, did not. Correspondingly, TPA tested positively as a promoter of transformation in a typical two-stage transformation assay with these cells while SAC did not. By altering the confluent-phase serum concentration and/or the medium renewal frequency of MCA-treated cultures, it was found that the magnitude of transformation for a given concentration of MCA was independent of the saturation density. Oscillations in this density were observed even when the medium was renewed as frequently as every 3 days, indicating that cell death and replacement occur during what is generally regarded to be a period of cellular stability. Neither TPA nor SAC blocked the cells from progressing into deeper resting states over time, as indicated by the prereplicative lag time after a medium change at 42 days. However, the serum concentration and medium renewal frequency did affect the resting state depth. Daily renewals with medium containing 10% serum blocked the resting state from deepening and kept the cells from achieving a saturation density. Under these circumstances, transformation was completely inhibited in MCA-treated cultures.—JNCI 1982; 68:259–266.

Whereas sustained hyperplasia by itself may be sufficient to promote tumors (*1*, *2*), the mechanism of the distinctly powerful tumor promoting action of certain hyperplastic agents such as the phorbol ester TPA (*3*) has not yet been established. One research area attracting considerable attention is the ability of phorbol esters to block cellular differentiation (*4*). The main contribution of TPA-type compounds to the promotion process might therefore involve keeping initiated cells from differentiating into nondividing cells (*5*, *6*) as opposed to their merely stimulating cell division.

Using the C3H/10T½ mouse embryo cell line for which a two-stage transformation assay has been developed (*7*), Mondal and Heidelberger (*8*, *9*) have shown that the ability of promoting compounds from different chemical classes to block the differentiation of these cells into either fat or muscle cells is inconsistent. However, for TPA-type compounds, there is a good correlation between promoting activity and ability to block both types of differentiation.

Another expression of differentiation in C3H/10T½ cells may be their ability to enter deeper resting states as the time spent in a confluent state increases, as indicated by lengthened prereplicative lag times after a stimulus to divide (*10*). This behavior is similar to that seen in other culture systems (*11–13*) and analogous to what occurs in a variety of aging organs (*14–16*). The elongation of the prereplicative period may be the consequence of the cells entering into deeper levels of the hypothetical resting state G_0 (*11*). Evidence from the literature suggests that this resting state is important to the process of promotion: 1) Croton oil shortens the total cell cycle time eightfold in mouse epidermis, with most of this shortening occuring in the G_1 portion of the cycle (*17*). Even though these authors do not refer to a G_0 compartment, it can be argued that the cells' G_1 residence time includes time spent in a G_0 state. 2) Retinoic acid, which can inhibit TPA's tumor promoting properties (*18*), increases the prereplicative lag time of HeLa cells relative to untreated cells (*19*). 3) TPA can substitute for PDGF, a serum polypeptide that confers upon resting phase 3T3 cells the competency to enter the cell cycle (*20*). Correspondingly, PDGF can block cycling cells from entering G_0 (*21*), an action for which TPA has not been tested. 4) In the initiation/promotion assay with C3H/10T½ cells, the promotion phase must begin before confluency is achieved (*7*, *22*), a time when the cells are beginning to acquire lengthened prereplicative lag times (*10*).

The above points led us to test TPA and SAC (a nonphorbol compound), which have been shown to promote transformation in C3H/10T½ cells (*7*, *23*), for their ability to interfere with cellular progression into G_0. We varied the serum concentration and medium renewal frequency in other experiments as an alternative method of manipulating

the resting state depth. We also measured the effects of these compounds and the medium renewal protocols on the saturation density. Conflicting data exist on TPA's effect on the saturation density of C3H/10T½ cells (*22, 24*); the effect of saccharin has not been studied. The measurements of resting state depth and cell density were compared to the transformation incidence in experiments where cells were given similar treatments after exposure to the carcinogen MCA.

MATERIALS AND METHODS

Cells.—C3H/10T½ CL8 mouse embryo fibroblasts were provided by Dr. Charles Heidelberger and Dr. Sukdeb Mondal. Our original stock was expanded and frozen according to Reznikoff et al (*25*), with the use of DMSO as the cryopreservative. Frozen cell stocks from passage 6 were thawed when needed and seeded into 150-cm^2 Costar or 75-cm^2 Falcon tissue culture flasks containing Eagle's basal medium with Earle's salts (GIBCO, Grand Island, N.Y.) supplemented with 10% heat-inactivated fetal calf serum (GIBCO). When the cultures were in their late growth phase they were rinsed with Ca^{2+}- and Mg^{2+}-free Hank's balanced salt solution. We then added 0.1% trypsin solution prepared from 2.5% stock trypsin (GIBCO) and the same salt solution, whose activity was quenched with serum approximately 6 minutes later. Samples were enumerated with a Coulter Counter (Coulter Electronics Inc., Hialeah, Fla.) and the cells were then suspended in medium with 10% serum to give the desired cell concentration. All of the experiments were performed in Costar 24-well (16-mm diameter) cluster dishes. The suspensions were stirred with an umbrella stirrer (Fisher Scientific Co., Rochester, N.Y.) at 1 rpm, and aliquots were dispensed into the wells using a repeatable pipetter (Manostat Corp., New York, N.Y.) fed from a sideport on the reservoir bottle. These procedures allowed an equal number of cells to be seeded into a large number of wells within a short time, ensuring uniform viability between the first and the last wells plated. The cultures were maintained at 37°C in a humidified incubator with 5% CO_2 atmosphere. Stock cultures were not exposed to antibiotics. In one experiment, as noted, cells were treated with gentamicin (Schering-Plough Corp., Kenilworth, N.J.) at 20 μg/ml after confluency, a concentration shown not to affect transformation in these cells (*26*). Serum from a single lot was used in all of the experiments and was added to the medium shortly before use. No serum was frozen and thawed more than twice. All solutions added to the cultures were prewarmed to 37°C. The cells tested negatively for mycoplasma contamination by means of Hoechst 33258 stain (American Hoechst Corp., North Sommerville, N.Y.) (*27*).

Cell counting.—The normal cell harvesting procedure with 0.1% trypsin in buffer solution (*25*) does not produce a complete yield when the cells have been confluent for extended periods. We found that a combined treatment with Na-EDTA and trypsin gave substantially improved harvests: the medium is poured off and the wells are preexposed to a 0.02% solution of Na-EDTA in Puck's salt solution (8.0 g NaCl, 0.4 g KCl, 1.0 g glucose, 0.35 g $NaHCO_3$, 1,000 ml H_2O) for approximately 1 minute (less for cells that are preconfluent or freshly confluent). This is replaced by Puck's saline containing both 0.02% Na-EDTA and 0.1% trypsin. Treatment continued until the majority of the cells were dislodged, at which time medium containing serum was added to quench the process, and the entire solution was then pipetted up and down against the bottom of the well several times to obtain a monodispersion. The entire suspension was diluted for counting in balanced electrolyte solution (Coulter Electronics, Inc.). A model ZB Coulter Counter with an attached Channelyzer was used to count the cells and to determine the median cell volume.

Transformation assays.—Cells were plated 100 per well in 0.5 ml medium containing 10% serum. After 24 hours this was replaced by 0.5 ml of fresh 10%-serum-containing medium that included the carcinogen MCA (Sigma Chemical Co., St. Louis, Mo.). The MCA was dissolved in acetone earlier to give a final concentration of 0.5% acetone in the medium. The treated wells and their acetone controls were rinsed with fresh medium 24 hours later and refilled with 0.5 ml of fresh medium. The medium was replaced again 4 days later, this time with 1 ml fresh medium per well. When the cultures became confluent, a medium change was made, and at this time the serum concentration of the medium in some wells was changed from 10 to 3%. Medium changes were then made at half-, 1-, or 4-day intervals for the remainder of the experiment.

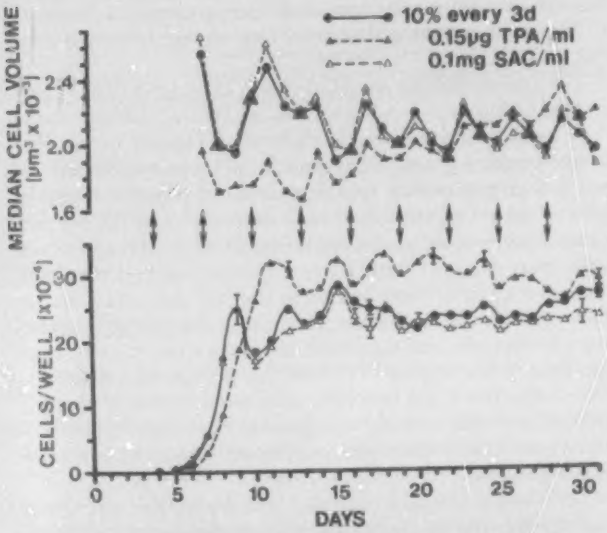
In the initiation-promotion experiment, TPA (Consolidated Midland Corp., Brewster, N.Y.) or purified type C SAC (provided by Dr. D. R. Stoltz, Department of Health and Welfare, Canada) were incorporated into the medium changes. TPA or SAC addition started 4 days after treatment with subtransforming concentration of MCA. TPA was dissolved in acetone and added to the medium to yield 0.5% acetone concentration, whereas SAC was added in a freshly prepared, filter-sterilized, aqueous solution. The medium contained 10% serum throughout the experiment and was changed at 4-day intervals.

The concentrations of MCA, TPA and SAC were nontoxic as determined by plating efficiency studies. The wells were scored for type III foci (*28*) 6 weeks after plating, after fixing the cells with methanol and staining with Giemsa. In one experiment, the wells were checked for foci every 2 to 3 days after confluency using a phase-contrast inverted microscope.

Autoradiography.—To determine if TPA, SAC, or altered serum concentration or medium renewal frequencies could interfere with the deepening of the resting state over time, wells treated identically to those in transformation experiments but not exposed to MCA were stimulated to divide at 42 days by a medium change incorporating 15% of serum. At 3-hour intervals, stimulated and unstimulated wells were pulse-labeled for 30 minutes with medium containing 5 μCi [^{3}H]thymidine/ml, (1 mCi/ml, 43-45 μCi/mmol; Amersham Corp., Arlington Heights, Ill.), followed by a 10-minute chase with medium containing 20 μg/ml unlabeled thymidine. The cells were then rinsed with a 0.9% NaCl solution and subsequently fixed in methanol-0.9% NaCl (1:1) solution followed by 100% methanol. After drying, the well bottoms were punched out and mounted on glass microscope slides with Permount (Fisher Scientific Co., Rochester, N.Y.), allowed to set, and coated with Kodak nuclear emulsion NTB 3 diluted 50% with water. The preparations were air-dried and exposed for 2 days in the dark, at which time they were developed and counterstained with Giemsa. At least 500 nuclei were scored per well.

RESULTS

Daily cell counts of wells that were treated with SAC or TPA, at concentrations shown to promote transformation in these cells (*7, 23*), are displayed in text-figure 1 relative to cell counts of untreated wells. The medium was renewed every 3 days. TPA treatment caused an initial lag in cell growth, as seen previously in this (*24*) and other systems (*29*), but the cells eventually grew to a higher saturation density than either the untreated or SAC-treated cells. This latter group may have had a slightly depressed cell density late after reaching confluency. TPA also produced a decrease in cell volume, as has been documented with many cell types (*29, 30*), but this effect diminished with time. We observed the ability of confluent-phase medium renewals to produce oscillations in the saturation density and cell volume not previously described in the literature. In general, volume increases followed the medium changes by 1 day, followed a day later by a coincident decline in the volume and an increase in the cell number. This is especially noticeable in the case of TPA-treated wells, whereas the effect on untreated and SAC treated wells appears to taper off after a few medium changes. The experimental results in text-figure 4 show a similar pattern for the groups receiving medium renewals every 4 days.

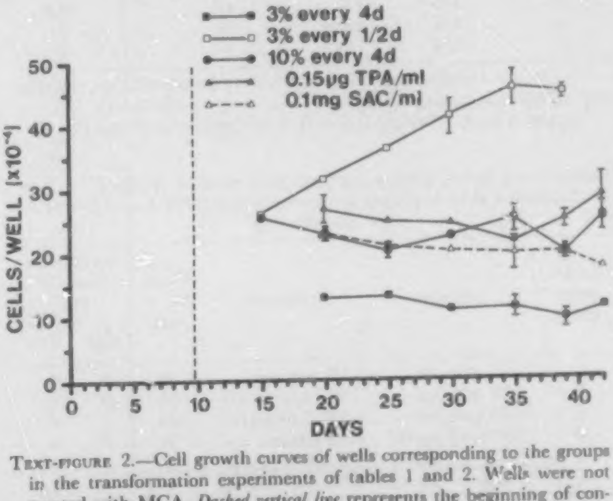


Text-figure 1.—Cells were seeded at 400/well in 1 ml of medium containing 10% serum. Indicated treatments were included in the medium starting with the first medium change (day 4) and continued for the duration of the experiment. Medium changes, *indicated by the arrows*, were at 1 ml/well and included 10% serum. Control wells contained 0.5% acetone starting with the first medium change. *Each point* on the cell growth curve represents the average of 3 wells. The SE for these points is shown where >10,000. Median cell volume was determined from the cumulative cell size distribution of the 3 wells.

Cell counts of wells not exposed to MCA (text-fig. 2), but otherwise treated identically to wells from accompanying transformation experiments, shows a similar increase in the saturation density for TPA-treated cells compared to untreated cells. In this experiment, the effects of confluent-phase serum concentration and medium renewal frequency were also measured. The saturation density is usually considered to be determined by the concentration of serum in the medium (*31, 32*). However, this text-figure shows that the frequency of the medium renewals can also have a substantial effect upon the saturation density. Cells given twice daily changes of medium containing 3% serum starting at confluency reached a 4.5-times greater saturation density than that achieved by the group given 3% serum-containing medium every 4 days. The 3% serum per half-day group also outgrew twofold the wells receiving 10% serum with medium changes every 4 days.

Results from transformation experiments corresponding to the groups in text-figure 2 are shown in tables 1 and 2. The first table shows that there were no statistically significant differences in transformation between groups on different medium renewal protocols in spite of their widely different saturation densities, although the highest density group (3% serum per half-day) showed a tendency toward enhanced transformation. The effect of administering TPA or SAC to initiated cultures is shown in table 2. The magnitude of TPA's ability to enhance transformation contrasts with its modest ability to stimulate cell growth. The inability of SAC to increase the saturation density was parallelled by its ineffectiveness as a promoter in our experiments. This was a surprising finding, since we used the same concentration that had previously been shown to produce a substantial increase in transformation (*23*). We obtained our SAC supply from the same source as those researchers.

At 42 days, corresponding to the termination of the



Text-figure 2.—Cell growth curves of wells corresponding to the groups in the transformation experiments of tables 1 and 2. Wells were not treated with MCA. *Dashed vertical line* represents the beginning of confluency. MCA-treated wells became confluent at about the same time. *Each point* is the average of 2 wells and the SE is given where >10,000. Wells were continuously treated with 20 µg/ml gentamicin starting with the medium changes at day 14.

transformation assays, representative wells from all of the groups were evaluated for their resting state depth (text-fig. 3). Countering our hypothesis, neither TPA nor SAC had an effect upon the movement of cells into deeper resting states with time. However, it appeared that the confluent-phase serum concentration and medium renewal frequency could influence this progression.

A second group of experiments investigated further the relationships between resting state depth, cell growth and transformation by manipulating these two culture conditions. As with the first set of experiments, a 10% serum per 4-days group and a 3% serum per 4-days group were included. The previous 3% per half-day group was replaced by a 3% per day group, and a 10% per day group was added. Cell counts of wells maintained under these culture conditions are shown in text-figure 4. By changing the medium every day starting at confluency, wells receiving 10% serum failed to stop growing over the course of the experiment, ultimately achieving a density of 7.2×10^5 cells/well at day 42, or 3.2-times the saturation density for cells receiving the same serum concentration but with medium changes every 4 days. This latter group, as well as both 3% serum groups, had cell densities at 42 days that were similar to their respective saturation densities achieved during the daily counting period. The 3% per day group reached a saturation density almost the same as that for the 10% per 4-days group. The 3% and 10% per 4-days groups showed the same oscillatory pattern for cell number and volume relative to medium changes as did the groups in text-figure 1. The wells receiving daily medium changes did not show this periodicity.

TABLE 1.—*Effect of altering the confluent-phase serum concentration and medium renewal frequency on the appearance of type III foci in wells treated with MCA and scored 6 wk after plating*[a]

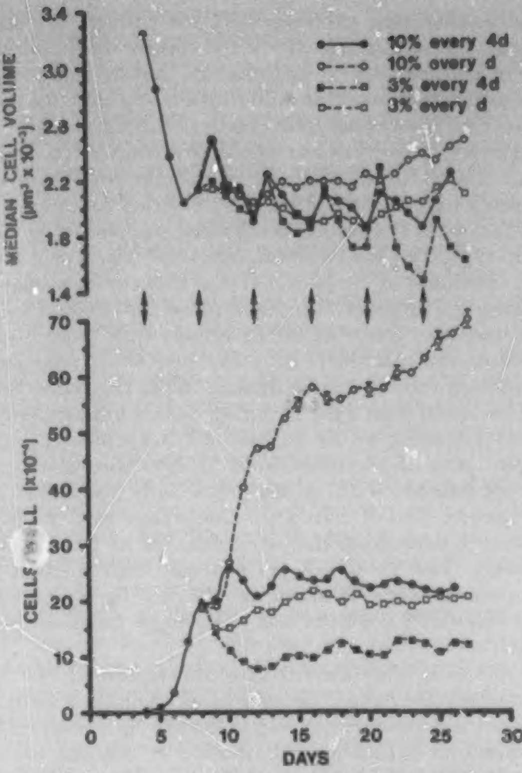
TEXT-FIGURE 3.—Wells corresponding to the groups in the transformation experiments of tables 1 and 2 were tested at day 42 for their resting state depth as reflected by the prereplicative lag time after a medium change incorporating 15% serum. *Each point* represents a 30-min uptake of [^{3}H]thymidine. Wells were not treated with MCA. The curves are presented on separate graphs for clarity. Unstimulated wells had the following average nuclear labeling indices: 3%/4 days, 0.0%; 3%/half-day, 1.2%; 10%/4 days, 0.2%; TPA, 0.1%, SAC, 0.1%.

The corresponding transformation experiments were performed using two concentrations of MCA. Table 3 shows that focus formation was completely inhibited in the 10% serum per day group, whereas the 10% per 4-days and 3% per 4-days groups had similar degrees of transformation in spite of their different saturation densities. The 3% per day group had a significantly higher percentage of transformed wells than either of these latter 2 groups, yet had about the same overall saturation density as the 10% per 4-days group. These results confirmed the previous findings that transformation does not correlate with the saturation density. Also apparent from a comparison of the groups which showed transformation is the lack of a correlation between transformation and the cumulative growth that each group has undergone before settling at its respective saturation density (text-fig. 4).

Text-figure 5 shows that the 10% serum per day group had the shortest lag time prior to replication for any group in this text-figure or in text-figure 3. This lag is virtually identical to what we have seen previously for cultures which have just become confluent (approximately 16 hr median lag time) (*10*). This indicates that the culture conditions were such that cells had not progressed into deeper resting states even after 4½ weeks in a confluent state. The 3% serum per half-day group of text-figure 3 had the shortest



TEXT-FIGURE 4.—Cells were seeded at 400/well in 1 ml of medium containing 10% serum. Starting at confluency (day 8), the medium changes were made with the indicated serum concentration and frequency. Medium change preceding confluency (day 4) included 10% serum and was performed on each group. All medium changes were made at 1 ml/well and are indicated for groups receiving changes every 4 days (*arrows*). *Each point* on the cell growth curve represents the average of 3 wells. The SE is shown where >10,000. Median cell volume was determined from the cumulative cell size distribution of the 3 wells.

prereplicative lag time of any of the groups that showed transformation in either experiment. However, this lag was still 3–6 hours longer than that indicated above for freshly confluent cells or for the 10% serum per day group in text-figure 5.

DISCUSSION

Even though neither TPA nor SAC prevented the cultures from acquiring longer prereplicative lag times, it is still possible that promoters selectively block initiated cells from going into deeper resting states. This is an effect that studies such as these, which measure population response, would be unable to discern. Sivak's study (*33*) on the ability of phorbol ester-containing croton resin to cause selective outgrowth of virally transformed 3T3 cells when mixed with normal cells lends support to this possibility. Additionally, Schulte-Hermann et al. (*34*) have recently shown that cells in areas of liver that were rendered preneoplastic by carcinogen treatments are preferentially stimulated to proliferate by liver tumor promotors.

The various combinations of confluent-phase serum concentrations and renewal frequencies produced a range of saturation densities and cumulative cell division that did not relate in any consistent manner to the transformation incidence. By analogy, the small enhancement of the saturation density and cumulative cell division by TPA is not likely to explain its ability to stimulate transformation in these cells. In spite of this, the ability of a compound to stimulate cell growth in vitro, even if such action is only epiphenomenally linked to the promotion process, may be a prerequisite for promoting potency in vitro: SAC, which did not stimulate cell growth, did not promote transforma-

tion. While our work was in progress, Kennedy et al (*22*) reported similar results that the ability of TPA to increase radiation-induced transformation in these cells is not explained solely by the fact that it stimulates cellular proliferation.

An unexpected finding was the apparent requirement for a cellular progression into deep resting states for transformation to be expressed. Such a requirement may relate to the latent period in carcinogenesis. As shown in text-figure 6, the appearance of type III foci in the transformation experiment of table 3 was scored for every 2-3 days after confluency. A confluent period of at least 12 days was required before foci began to appear, during which time the cultures were presumably progressing into deep resting states.

We cannot readily offer an explanation of the reasons why the resting state depths of the 3% serum per 4 days groups in text-figures 3 and 5 varied so widely in spite of the groups being maintained as identically as practical. However, we do not think that it necessarily reflects the variability of this parameter for the other treatment groups nor does it detract from our conclusions. There was a good correspondence between the 10% serum per 4 days curves in the same text-figures. Furthermore, there is a consistent relationship between renewal frequency and resting state depth for each serum concentration (10% per day <10% per 4 days; 3% per half-day <3% per day <3% per 4 days).

The resting state depth of the transformation-inhibited 10% serum per day group, as well as being similar to that of freshly confluent cells (*10*), was also similar to the resting state depth of a chemically transformed cell line derived from C3H/10T½ cells reported by Moses et al. (*35*). Their results suggest that, unlike normal cells, transformed cells are unable to submerge into deeper resting states with time.

It is possible that carcinogen-treated cultures are able to express transformation only if the culture conditions allow the unaffected cells to progress into resting states beyond this apparent limit. This would then give a selective growth advantage to any transformed cells in the culture since these cells would be the first to respond to a stimulus to divide. A series of such stimuli might occur with the periodic medium renewals that maintain the cultures during confluency. The oscillations in the saturation density, seen for those groups with confluent-phase medium renewals every 3 or 4 days, is one indication of the potential that these renewals have for causing cell turnover. Confluent-phase cell division and cell loss were also probable in the groups with more frequent medium changes (half- or 1-day intervals), even though text-figure 4 shows that oscillations in the saturation density did not occur with daily renewals. This is indicated in text-figure 3 (legend) by the amount of DNA synthesis that was occurring in unstimulated wells 42 days after plating. The 3% per half-day wells, which presumably also lacked these oscillations, had at least a 6-times greater rate of [^{3}H]thymidine-incorporation than either the 3% or 10% per 4 day cultures. The 3% serum per half-day cells reached their saturation density by about day 39 (text-fig. 2), indicating that this DNA synthesis was likely to be balanced by cell loss.

Since daily renewals with medium containing 10% serum apparently prevented the cells from reaching a saturation density, it is possible that type III focus formation requires a minimum period in such a state in contrast to, or in concert with, a minimum resting state depth. Again, periodic medium changes while the cells are at their saturation density may provide a stimulus for the selective outgrowth of carcinogen-altered cells. In a careful study of cell density kinetics, Van Der Bosch (*36*) demonstrated that graduated cell death is a normal means by which cultures adjust to reduced serum levels. The cell turnover we have described is possibly then a consequence of a differential in the potency of fresh medium versus medium that has become partially depleted of serum components after a time in culture, in terms of its ability to sustain all of the cells in a viable state. It is known that transformed cells have a lower serum requirement for growth than their normal counterparts (*35*), thus normal cells may be preferentially lost during these die-off periods. Another possibility is that the confluent cells release a growth-inhibiting factor such as FGRF (*37*) that counteracts the ability of serum to maintain cells at a particular density. FGRF does not restrict virally transformed cells, making this another means by which nontransformed cells could be discriminated against. Both of these proposed mechanisms can also be used to explain the effect that frequent medium renewals have upon the overall cell density. Increased renewal frequencies could prevent either nutrient deprivation or accumulation of growth inhibitory factors, or both. Furthermore, FGRF has been shown to delay the onset of DNA synthesis in resting cultures, with higher concentrations causing greater delays (*37*). This may explain our observation that frequent medium renewals slow the progression of cultures into deeper G_0 states, possibly by keeping such factors from accumulating. It may also be that resting state deepening occurs only after the cells have reached their saturation density—something that is delayed by frequent medium renewals.

The inhibition of transformation seen in the 10% serum per day group is unlikely to be a consequence of the high cell density it achieved: There was no indication from the other groups of either experiment of an inverse correlation between the saturation density and transformation incidence. This would initially appear to be in conflict with the results by Bertram (*32*), where lowered serum levels reduced the saturation density and enhanced transformation in C3H/10T½ cells, while high serum levels increased the saturation density and inhibited transformation. However, there are circumstances that may account for this discrepancy: 1) We do not know how the growth-promoting properties of our serum compare with the serum used by Betram, who also showed that different serum lots produce widely different saturation densities, especially at low concentrations; 2) The medium renewal interval in his experiments was 7 days in comparison with our maximum of 4 days. We have noticed that the cell die-off becomes greater as this interval increases. The relationship between saturation density and transformation incidence may increasingly become obscured as the renewal interval is lengthened.

Type II foci were discernible in a small number of the 10% per day wells. Their occurence was inhibited nonetheless compared to the other MCA-treated groups from the same experiment. However, their detection makes it unlikely that the high cell density achieved in the 10% per day group obscured the identification of foci. It also suggests that this lower grade of transformation is not as sensitive to the conditions that blocked the appearance of type III foci.

From replating experiments with C3H/10T½ cells, Haber et al. (*38*) conclude that transformation is independent of the absolute time or number of cell divisions occurring between carcinogen treatment and expression. Our experiments indicate that cell division occurs in confluent cultures that receive periodic medium renewals even after they have reached their saturation density. Cultures reaching this growth plateau are usually considered to be dormant but are actually more likely to be in a state in which cell division and loss are balanced. Cell turnover during this period may be required for the expression of transformation, thus providing a selective growth stimulus for initiated or transformed cells that does not exist when the cells are in a preconfluent growth phase.

Vasopressin: Action on WRK-1 Rat Mammary Tumor Cells[1]

M. E. Monaco,[2,3] **P. H. Kohn,**[4] **W. R. Kidwell,**[5] **J. S. Strobl,**[6] *and* **M. E. Lippman**[7]

ABSTRACT—WRK-1, a cell line in long-term culture derived from a 7,12-dimethylbenz[a]anthracene-induced rat mammary tumor, responds to physiologic concentrations of vasopressin with increased precursor incorporation into phospholipids and with increased protein accumulation. Because vasopressin has been reported to be a potent mitogen for Hela cells and 3T3 cells, a study was conducted to determine whether it could act as a mitogen for WRK-1 cells. Under no conditions was a clear-cut mitogen response to vasopressin demonstrated.—JNCI 1982; 68:267–270.

In recent years vasopressin has been reported to have activities other than antidiuresis and pressor that may have physiologic relevance. Its ability to stimulate smooth muscle contraction in the breast and uterus under certain conditions has been well documented (*1, 2*). A role for vasopressin as a neurotransmitter has been suggested by the findings of Walter and his colleagues (*3*); Hems and Whitton (*4*) and Kirk et al. (*5*) have reported effects of vasopressin on liver metabolism. Lastly, vasopressin can act as a potent mitogen for Hela cells (*6*) and 3T3 cells (*7*). The mitogenic activity has led to speculation concerning a role for vasopressin in cancer growth (*8*).

We have recently reported the establishment and characterization of WRK-1, a cell line derived from a DMBA-induced rat mammary tumor (*9–11*). Morphology and response to neurohypophyseal hormones suggest these cells may be of myoepithelial origin. Physiologic concentrations of vasopressin (10^{-10} *M*) and pharmacologic concentrations of oxytocin (10^{-8} *M*) stimulate a variety of metabolic alterations in WRK-1 cells: 1) increased incorporation of [^{14}C]-acetate into fatty acids (*11*), 2) increased rate of turnover of phosphatidylinositol (Monaco ME, Lippman ME: Manuscript in preparation), and 3) increased protein accumulation (*11*). The fact that the protein concentration is increased as well as the observation that the radiolabeled fatty acids are present predominantly as phospholipids suggested that vasopressin acts as a mitogen for these cells.

MATERIALS AND METHODS

Carrier-free [^{32}P]orthophosphate was obtained from ICN Pharmaceuticals Inc. [^{33}P]orthophosphate was from New England Nuclear Corp. [^{3}H]thymidine (45 Ci/mmol) and [^{14}C]acetate (59 mCi/mmol) were supplied by Amersham/Searle Corp. Normal rat serum and fetal calf serum were from Grand Island Biological Co. Tissue culture media, trypsin solutions, and Dulbecco's PBS were prepared by the National Institutes of Health Media Unit. BrdUrd and colchicine were purchased from Sigma Chemical Co. Vasopressin was obtained from Calbiochem-Behring Corp. Aquasol came from New England Nuclear Corp.

Cell culture.—WRK-1 cells were derived from a DMBA-induced rat mammary tumor as previously described (*9*). The morphology, growth characteristics, and response of these cells to neurohypophyseal hormones have also been described (*10*). Cells were routinely grown in MEM supplemented with glutamine (1.168 mg/ml), penicillin (100 U/ml), streptomycin (100 µg/ml), fetal calf serum (10%), and rat serum (2%). This growth medium will be referred to as complete medium. For experiments, cells were harvested with trypsin (0.05%) and EDTA (0.02%) solution in PBS without Ca^{2+} or Mg^{2+} and replicately plated into six-well (35 mm/well) plastic dishes or 100-mm plastic petri dishes in 2 ml or 10 ml complete medium, respectively. When the cells had attached to the surface of the dish, the complete medium was exchanged for the experimental media, as described in the text-figure legends.

Measurement of [^{33}P]orthophosphate incorporation.—Cells were replicately plated in complete medium containing 10 µCi [^{32}P]orthophosphate/ml. After 48 hours, half of the cultures was treated with vasopressin (5×10^{-9} *M*), and [^{33}P]orthophosphate (10 µCi) was added to all the cultures. Cells were harvested 2 hours later with 0.02% EDTA in PBS and collected by centrifugation in a Clay-Adams serofuge II. Phospholipids were extracted from the cell pellets with chloroform:methanol:HOH (2:1:0.75, vol/vol/vol) as previously described (*11*). A fraction of the chloroform layer was transferred to a glass scintillation vial and allowed to evaporate to dryness in air. Aquasol, 5 ml, was then added to each sample, and the radioactivity was determined with a Packard liquid scintillation spectrometer (model #3044). Results are expressed as the ratio of ^{33}P/^{32}P.

Growth curves.— For growth experiments, cells were repli-

cately plated in 35-mm plastic wells. If complete medium was used for the duration of the experiment, vasopressin (5×10^{-9} *M*) was added to half the cultures at the time of plating. If a depleted medium was used, the complete medium was removed after the cells had attached to the surface of the dish and replaced with the depleted variant, plus or minus vasopressin. Cell numbers were determined with the use of a hematocytometer.

Measurement of thymidine incorporation.—After attachment of the cells to the dish, the complete medium was exchanged for serum-free medium supplemented with insulin (10^{-6} *M*). The medium was replaced 12 hours later with fresh medium with insulin, and vasopressin (5×10^{-10} *M*) was added to half the cultures. At various times following the addition of the hormone, cells were incubated for 2 hours with [^{3}H]thymidine (1 μCi/ml). Incorporation of [^{3}H]thymidine into acid-precipitable material was measured as previously described (*12*).

Measurement of mitotic index and BrdUrd incorporation.—Cells were replicately plated in 100-mm petri dishes in complete medium. When the cultures were approximately 50% confluent, the medium was exchanged for serum-free medium with insulin, and vasopressin (5×10^{-9} *M*) was added to half the cultures. BrdUrd (10^{-6} *M*) was added to all the cultures. At designated times, cells were treated for 4 hours with colchicine (200 ng/ml) and then harvested with 0.02% EDTA in PBS. Cells were collected by centrifugation and the pellets were treated at 37°C with 0.075 *M* KCl for 10 minutes. They were then fixed two times in cold methanol: acetic acid (3:1, vol/vol). Slides were prepared in a standard manner, air dried, and stained for sister chromatid differentiation as described by Goto et al. (*13*).

Protein determinations.—Protein concentrations were measured by the methods of Lowry et al. (*14*).

RESULTS

Effect of vasopressin on phospholipid metabolism in complete medium.—WRK-1 cells do not increase in number under the serum-free conditions generally employed when the effects of vasopressin are measured; therefore, to assess the mitogenic potential of the hormone, we first determined its ability to alter metabolism in cells under growth conditions. Stimulation by vasopressin of [^{32}P]orthophosphate incorporation into phospholipids was used as the end point of hormonal activity. Results are seen in table 1. Vasopressin treatment resulted in an 87% increase in ^{32}P incorporation above control values. In a second experiment (results not shown) stimulation was 50%. These values are approximately half those seen under serum-free conditions. A general increase in overall basal metabolic rates produced by serum probably explains the lesser folds of stimulation observed under these conditions.

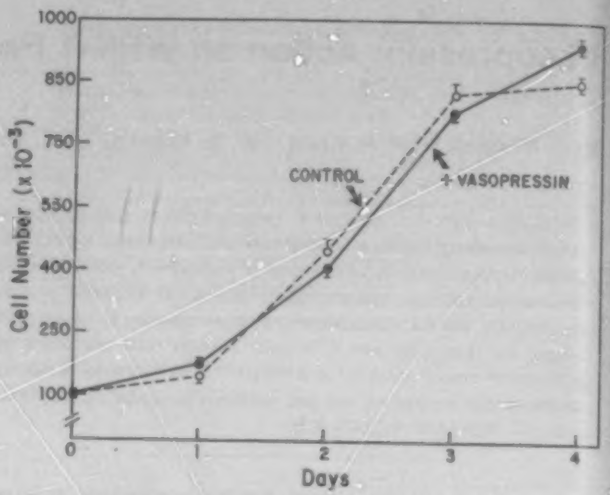
Cells with complete medium	^{32}P, cpm	^{33}P, cpm	^{32}P/^{33}P, × 10^3
Control	287	5,872	48.8
Vasopressin added	459	5,015	91.5

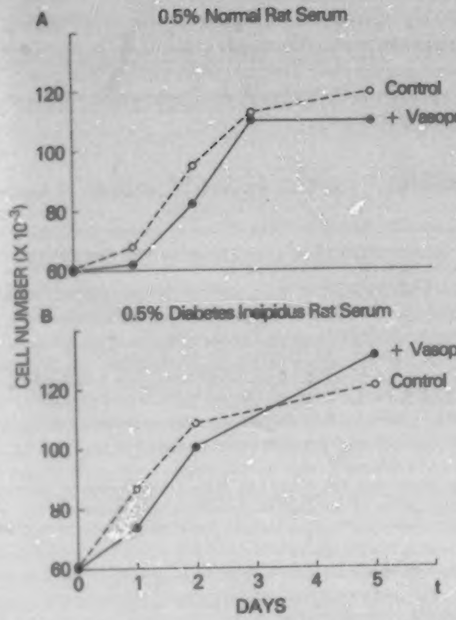


TEXT-FIGURE 1.—Effect of vasopressin on the growth of WRK-1 cells in complete medium. Cells were plated in MEM plus 10% fetal calf serum and 2% rat serum, plus or minus vasopressin. On days 1-4, cells were harvested and counted as described in "Materials and Methods." Controls, ○- - -○; cultures treated with 5×10^{-9} vasopressin, ●—●. Values are the means of three determinations ± 1 SD.

Effects of vasopressin on growth in complete medium.—Having ascertained that vasopressin is effective in the presence of complete medium, we studied growth under these conditions. Text-figure 1 illustrates the results. The cell number increased from 100,000 per dish at the start of the experiment to 850,000 per dish by day 4. No significant difference was seen between control and vasopressin-treated cells during this time.

Effect of vasopressin on growth in depleted medium.—Mitogenic actions of a growth agent are sometimes abolished in the presence of other mitogens. We, therefore, carried out growth experiments in depleted medium in which WRK-1 cells grew more slowly (doubling time=72 hr) than in complete medium. Two variations were made: 1) Serum concentrations were lowered to 0.5% rat serum and 0% fetal calf serum (text-fig. 2A) and 2) rat serum obtained from animals with hereditary diabetes insipidus (vasopressin deficiency) was substituted for normal rat serum (text-fig. 2B). In neither case did vasopressin increase the growth rate of the cells. The difference on day 5 seen in text-figure 2B was not statistically significant. When the ability of insulin to increase the growth rate of the cells was tested under identical conditions, the results shown in table 2 were obtained. Thus insulin increased the numbers of WRK-1 cells under conditions in which vasopressin did not.

Effect of vasopressin on growth parameters in serum-free medium.—Because maximal metabolic and morphologic effects of vasopressin are generally observed under serum-free conditions, mitogenicity was also assessed in serum-free medium containing insulin. Since cells do not divide under these conditions, three parameters other than cell number were used to assay the mitogenic capacity of vasopressin: *a*) [^{3}H]thymidine incorporation into acid-precipitable material, *b*) mitotic index, and *c*) BrdUrd incorporation into DNA. That the DNA was replicating under these conditions



TEXT-FIGURE 2.—Effect of vasopressin on the growth of WRK-1 cells in depleted medium. Cells were plated in complete medium. When the cells had attached, the complete medium was exchanged for MEM + 0.5% rat serum (A) or MEM + 0.5% diabetes insipidus rat serum (B). Cells were harvested and counted as described in "Materials and Methods." Controls, O---O; cultures treated with vasopressin, ●—●. Values given are means of triplicate determinations. SD averaged ≈10%.

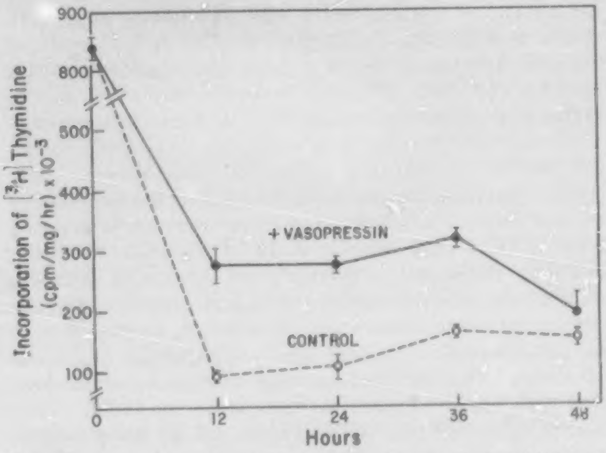
can be demonstrated by the appearance of BrdUrd-labeled chromosomes as described below.

a) [^{3}H]thymidine incorporation: The results of this experiment are misleading. Incorporation of [^{3}H]thymidine into acid-precipitable material was greater in the presence of vasopressin at a given time point; however, if one follows a time course of incorporation (text-fig. 3), one observes that vasopressin acted to decrease the rate at which cells slowed down metabolically following the removal of serum from the medium. Measurements of thymidine kinase activity paralleled those of thymidine incorporation (data not shown). Thus, rather than inducing mitosis, vasopressin probably increases the survival of the cells under adverse conditions. The appearance of the cells supports this notion.

b) Mitotic index: When the number of mitotic figures per 1,000 cells was compared for control and vasopressin-treated cells in serum-free medium, the results shown in table 3 were obtained. Whereas the mitotic index increased with time in culture, there was no stimulatory effect of vasopressin. The increase in the number of mitotic figures with time suggests that, in the absence of serum, cells are able to replicate their DNA but not divide. Possibly however, the rate of cell death is equal to the rate of cell division.

c) BrdUrd incorporation: Adding BrdUrd to thymidine-deficient medium leads to the incorporation of BrdUrd in place of thymidine into newly synthesized strands of DNA. Through a process of photolysis, heating, and subsequent staining with Giemsa, cells having DNA that has replicated once after BrdUrd addition (M1), twice after BrdUrd addition (M2), and three more times after BrdUrd addition (M3) can be distinguished by arresting the cultures in metaphase and observing the differential staining patterns of each type in a metaphase spread. M1 figures have two of four strands from each chromosome labeled with BrdUrd; M2 figures have three of four strands from each chromosome labeled; M3 figures have some chromosomes with three and others with all four labeled. When mitotic figures from control cells and vasopressin-treated cells were scored, the results shown in table 4 were obtained. Vasopressin had no effect on the distribution, indicating no difference in rates of DNA replication.



TEXT-FIGURE 3.—Effect of vasopressin on the incorporation of [^{3}H]thymidine into acid-precipitable material in WRK-1 cells. Cells were plated and allowed to attach to the surface of the dish in complete medium. The complete medium was exchanged for fresh serum-free medium with 10^{-6} *M* insulin, plus or minus vasopressin (5×10^{-9} *M*). At the time indicated, cells were incubated with 1 μCi/ml [^{3}H]thymidine for 2 hr and harvested as described in "Materials and Methods." Control cells, O---O; vasopressin-treated cultures, ●—●. Values are means of triplicate determinations ±1 SD.

DISCUSSION

Vasopressin has been reported to act as a mitogen for both Hela cells (*6*) and 3T3 cells (*7*) in culture. We (*10, 11*) have previously reported that WRK-1 rat mammary tumor cells respond to vasopressin with a variety of biochemical alterations. To determine whether or not vasopressin was a mitogen for WRK-1 cells, we performed the preceding series of experiments. Under no conditions were we able to detect a clear-cut mitogenic effect of the hormone. No consistent differences were seen in cell number, mitotic index, or rate of DNA replication. Thymidine incorporation was higher in vasopressin-treated cells; however, the time course suggested that under serum-free conditions vasopressin was increasing the survival of the cells rather than stimulating growth. In similar experiments, insulin (10^{-6} *M*) clearly increased cell number. The possibility of endogenous serum vasopressin masking the effect of added hormone was ruled out by experiments in serum-free medium, by experiments in medium containing serum from animals with diabetes insipidus, and by the fact that vasopressin could stimulate precursor incorporation into phospholipid in the presence of normal serum. The exact nature of vasopressin's interaction with WRK-1 cells remains to be determined. However, although vasopressin is probably not a mitogen for these cells, a role for this hormone in cancer growth cannot be eliminated. Vasopressin may, for example, predispose cells for mitogenization by other agents or influence metastatic potential. Other morphologic and biochemical data show that vasopressin increases the survival of the WRK-1 cells and as such may play an important role in the growth of cancers. Factors that influence cancer growth in vivo need not be directly mitogenic. Certainly, the relationship between vasopressin and mammary cancer cells is worthy of further investigation. We are currently attempting to dissect the mechanism by which vasopressin stimulates overall metabolism in WRK-1 cells.

Cholangiocellular Carcinomas Induced in Syrian Golden Hamsters Administered Aflatoxin B_1 in Large Doses[1,2,3]

Michael R. Moore,[4,5] Henry C. Pitot,[4] Elizabeth C. Miller,[4,6] *and* James A. Miller[4,7]

ABSTRACT—The hepatocarcinogenicity of aflatoxin B_1 (AFB_1) was compared in male Syrian golden hamsters and inbred F344 rats. AFB_1 was administered by gavage 5 days/week for 6 weeks at doses of 1 and 2 mg/kg body weight/day to rats and hamsters, respectively; rats did not survive beyond 3 weeks with doses of 2 mg/kg/day. After 6 weeks the animals either received no further treatment or were given 0.1% phenobarbital sodium in the drinking water. ATPase-deficient foci of hepatic parenchymal cells, neoplastic nodules, and hepatocellular carcinomas were observed in liver sections from AFB_1-treated rats killed at 6, 14, or 23 weeks; they were not seen in sections from AFB_1-treated hamsters killed at 6, 14, or 46 weeks. Each of the 50 AFB_1-treated rats developed hepatocellular carcinomas by 46 weeks; many also had cholangiocarcinomas and mixed hepatocellular–cholangiocellular carcinomas. Hepatocellular carcinomas were found in only 2 of 49 AFB_1-treated hamsters by 78 weeks. At this time cholangiocarcinomas were found in 15 hamsters, and microscopic cholangiomas were seen in all of the livers. Compared to the rat, the hamster was resistant to the hepatotoxic and hepatocellular carcinogenic effects of AFB_1.—JNCI 1982; 68:271–278.

Considerable evidence indicates that in the rat AFB_1-2,3-oxide is an ultimate electrophilic, mutagenic, and carcinogenic metabolite of the hepatocarcinogenic mycotoxin AFB_1 (*1–5*). The capacity of fortified liver microsomes from adult male Syrian golden hamsters to metabolize AFB_1 to AFB_1-2,3-oxide in vitro, as measured by the yields of 2,3-dihydro-2,3-dihydroxy-AFB_1 or of aflatoxin–nucleic acid adducts, is equivalent to that of hepatic microsomes from phenobarbital-treated male F344 rats and about four times that of hepatic microsomes from untreated rats (*5–7*). However, in spite of this high enzymatic activity in vitro, hamsters given AFB_1 form lower levels of hepatic nucleic acid-bound aflatoxin adducts in vivo than do rats given AFB_1 [(*8*); Moore MR, Miller EC, Miller JA: Unpublished data].

The acute hepatotoxicity of AFB_1 is also somewhat lower for the hamster than for the rat; a median lethal dose of 10 mg/kg body weight was reported for 30-day-old hamsters as compared to that of 5 mg/kg body weight for 21-day-old male rats (*9*). Furthermore, in contrast to the high susceptibility of rat liver to the carcinogenicity of AFB_1 (*10*), in early studies no hepatic tumors, regenerative nodules, or cirrhosis was observed in Syrian hamsters given a mixture of aflatoxins (total doses of 5–10 mg; ≈40% AFB_1) over 6–11 months and maintained for their life-span (≤30 mo) (*11*). Some histopathologic changes were noted in the hamster tissues, but more recent studies have shown that dimethylformamide, the solvent used in the previous study (*11*) for the ip administration of the aflatoxins, is also hepatotoxic (*12, 13*). To examine this problem further, we have given high doses of AFB_1 orally for 6 weeks to weanling male Syrian hamsters and F344 rats; the histopathologic changes in the livers and tumor induction were studied as a function of time. Although considerably more resistant than rats to the hepatotoxic and hepatocarcinogenic effects of AFB_1, the treated hamsters developed cholangiomas and cholangiocarcinomas, in addition to cholangiofibrosis and cystic changes, by 32–78 weeks.

MATERIALS AND METHODS

Male Syrian golden hamsters and F344 rats, both 4 weeks old (Charles River Breeding Laboratories, Wilmington, Mass.), with average initial weights of 54±6 and 66±8 g, respectively, were housed in pairs in screen-bottom cages and fed Wayne Breeder Blox pellets (Allied Mills, Inc., Chicago, Ill.) and tap water ad libitum.

AFB_1 (Calbiochem, La Jolla, Calif.), dissolved in DMSO and diluted with an equal volume of sterile trioctanoin (Sigma Chemical Co., St. Louis, Mo.), was given by gavage without anesthesia 5 days/week for 6 consecutive weeks. The daily dose for the hamsters was 2 mg/kg body weight, and that for the rats was either 1 or 2 mg/kg body weight. Control animals of both species received only the vehicle, 50% DMSO–trioctanoin, on the same schedule. All animals received 2 ml of DMSO–trioctanoin/kg/day. Uniform suspensions were maintained by use of a magnetic stirrer. Starting 24 hours after the last dose of AFB_1 or solvent, we

gave some of the animals 0.1% phenobarbital sodium in the drinking water (*14*) until the experiments were terminated.

At least 6 rats/group were killed at 6, 14, and 23 weeks after the beginning of treatment, and at least 6 hamsters/group were killed at 6, 14, and 46 weeks. For the 6-week time point the animals were all killed 24 hours after receiving the last of the 30 doses of AFB_1 or solvent. In addition, groups of 30 rats or hamsters were observed for tumor development; the surviving rats and hamsters were killed at 46 and 78 weeks, respectively. At each time both AFB_1-treated and control animals were autopsied. The hamsters and rats killed at or after 23 weeks included groups given phenobarbital in the drinking water, starting at the 7th week, and groups given only tap water.

All animals found dead and those killed at the times indicated above were subjected to gross routine autopsies, which included examination of the skin and subcutaneous tissue and the organs of the abdominal and peritoneal cavities. Sections of the livers from all animals, of the harderian glands and kidneys from the animals killed at the specified intervals, and of the harderian glands from the hamsters that survived to the end of the experiment were fixed in buffered 10% Formalin and stained with H & E for histologic examination. The histopathologic criteria for the diagnosis of hepatic lesions, including the cholangiocellular neoplasms, were those of the IARC (*15*) and of the National Research Council (*16*).

For the animals killed at one of the designated times, each liver lobe was bisected and one of the two sections from each lobe was fixed in buffered 10% Formalin. The remaining sections from each of the liver lobes were juxtapositioned on a filter paper square to form a single tissue block, which was immediately frozen on Dry Ice. Consecutive 6-μm sections with areas approximately 3 cm^2 from the frozen tissues were stained for ATPase (*17*) or with H & E. In addition, four consecutive sections cut from frozen tissue blocks from the livers of a few of the tumor-bearing animals were stained for ATPase, Glc-6-Pase (*18*), or GGT (*19*) or with H & E. The size and total number of ATPase-deficient foci per liver were estimated as described previously (*20, 21*).

RESULTS

The rats were much more susceptible to the hepatotoxic and hepatocarcinogenic effects of AFB_1 than were the hamsters. Thus none of the rats given 5 doses of AFB_1/week at the rate of 2 mg/kg/dose survived past the 3d week; the livers of these rats all showed moderate bile duct proliferation and portal fibrosis, as well as focal areas of atypical hepatocyte proliferation. The 6-week survival rates of the rats given doses of 1 mg/kg and of hamsters given doses of 2 mg/kg, five times per week for 6 weeks, were 95 and 85%, respectively; 100 and 88% of the control rats and hamsters, respectively, given only the vehicle survived for this period. The weight gains of the AFB_1-treated (1 mg/kg/dose) and control rats during the 6-week treatment period were 83 and 141 g, respectively. During the same period the AFB_1-treated hamsters gained 30 g, while the control hamsters gained 83 g. These weight differentials were essentially eliminated during the next 8 weeks because the AFB_1-treated animals, with or without phenobarbital administration, had weight gains of 1.5–2 times those of controls. These large doses were administered in view of the reported refractoriness of hamsters to the induction of hepatic tumors by AFB_1 (*11*).

The results of the gross and histologic studies of the livers, kidneys, and harderian glands indicated that, as in previous studies with rats (*10*), the pathologic changes induced by AFB_1 occurred primarily in the liver. The hepatic damage occurred earlier and was more severe in rat liver than in hamster liver. Further, the hepatic toxicity resulted in cholangiofibrosis, cholangiomas, and cholangiocellular carcinomas in the hamsters, whereas the hepatic parenchymal cells were the major target in rat liver.

Liver Pathology at 6 Weeks

At 24 hours after the last of 30 doses (1 mg/kg) of AFB_1, rat liver sections stained with H & E showed numerous transections of both eosinophilic and basophilic foci (*16*) of hepatic parenchymal cells (table 1; figs, 1, 2). Several transections of neoplastic nodules (*22*) were noted in sections from four of six livers examined. The livers were also calculated (*20, 21*) to contain an average of 2,110±1,050 ATPase-deficient foci of parenchymal cells; the foci had an average diameter of 0.34±0.19 mm. Since a deficiency in ATPase was evident throughout the tissue sections, only those focal areas devoid of any ATPase staining were counted. Moderate ductular proliferation and focal hepatocyte degeneration, predominantly around the portal areas, were noted in all the sections. Occasional areas of moderate to marked oval cell proliferation and focal megalocytosis were detected. Liver sections from rats given only the vehicle were free of any notable abnormalities.

In contrast, neither neoplastic nodules nor any transections of eosinophilic or basophilic foci of parenchymal cells were seen in H & E-stained liver sections from hamsters given AFB_1 at 2 mg/kg/dose—twice the level tolerated by the rats (table 1). Furthermore, at 6 weeks no ATPase-deficient foci of hepatic parenchymal cells were seen in liver sections from AFB_1-treated hamsters or in the vehicle controls. Pathologic changes common to the livers from AFB_1-treated hamsters killed at 6 weeks (24 hr after the last dose) included focal hepatocyte degeneration and a marked accentuation of acinar zone 1 (*23*) with occasional megalocytosis (fig. 3). These changes were not seen in liver sections from control hamsters given only the vehicle (50% DMSO–trioctanoin) (fig. 4).

Liver Pathology at 14 Weeks

At 14 weeks after the first dose of AFB_1, multiple gray-white nodules about 1 mm in diameter were detected on the surface and in the interior of the liver lobes of all carcinogen-treated rats; transections of eosinophilic foci of hepatic parenchymal cells and of neoplastic nodules (fig. 5) were prevalent in virtually all of the sections examined microscopically (table 1). Microscopic hepatocellular carcinomas were observed in liver sections from 3 of the 9 rats. The livers contained an average of 3,440±535 ATPase-deficient foci with an average diameter of 0.76±0.48 mm.

No foci of ATPase-deficient parenchymal cells and no eosinophilic or basophilic foci were detected in the liver sections from AFB₁-treated hamsters or from vehicle-treated controls killed at 14 weeks. Focal megalocytosis and cellular vacuolization were the only notable abnormalities seen at 14 weeks (8 wk after the last dose) in liver sections from hamsters given AFB₁ (fig. 6).

Liver Pathology at 23 Weeks

As table 2 shows, 23 weeks after the first dose of AFB₁, all of the livers from the AFB₁-treated rats contained one or more gray-white nodules that were at least 0.5 cm in diameter and that were diagnosed microscopically as hepatocellular carcinomas. These carcinomas exhibited a histologic pattern similar to that of the Morris hepatoma 7316 (*24*). In addition, the livers also frequently contained multiple hyperplastic and neoplastic nodules (*22*). Administration of 0.1% of phenobarbital sodium in the drinking water did not increase the tumor incidence. No cholangiocarcinomas were detected in the livers from AFB₁-treated rats, and no significant abnormalities were observed in liver sections from control rats given only 50% DMSO–trioctanoin with or without subsequent phenobarbital administration.

[a] AFB₁ was given daily, 5 days/wk, for 6 wk to rats at a level of 1 mg/kg/day and to hamsters at 2 mg/kg/day. Controls for both species were given only the vehicle. Beginning 24 hr after the last dose, 1 group of rats and 1 group of hamsters were given 0.1% phenobarbital sodium in the drinking water until the experiment was terminated. Formalin-fixed liver sections stained with H & E were examined from all rats killed at 23 or 46 wk, hamsters killed at 46 or 78 wk, and animals of either species that were found moribund or dead.

[b] Data for groups of 30 rats designated in the protocol for analysis of tumor incidence. None of the rats killed at 6, 14, or 23 wk are included in these tabulations.

[c] Data for groups of 30 hamsters designated in the protocol for analysis of tumor development. None of the hamsters killed at 6, 14, or 46 wk are included in these tabulations.

[d] + = phenobarbital was administered as 0.1% of the drinking water starting at 7 wk. – = phenobarbital was not administered.

[e] Tumors ≥0.5 cm in diameter were tabulated.

Liver Pathology at 46 Weeks

Twenty-five of the 30 AFB_1-treated rats in each group, whether or not they were given phenobarbital in the drinking water, survived until they were killed at 46 weeks (table 2). Gray-white nodules that were at least 0.5 cm in diameter and were diagnosed microscopically as hepatocellular carcinomas were found in the liver of each of the treated rats; the average number per liver was 7. However, the number of rats that also had mixed hepatocellular–cholangiocellular carcinomas (18/25 or 72%) or cholangiocellular carcinomas (5/25 or 20%) (*15*) was greater for the AFB_1-treated rats given phenobarbital than for those not given the drug. The incidences of these tumors in the rats not given phenobarbital were 5 of 25 (20%) and 2 of 25 (8%), respectively. Liver sections from controls treated only with the DMSO–trioctanoin emulsion, whether or not they received phenobarbital, showed no remarkable abnormalities.

In contrast, hepatocellular carcinoma was not detected in any of the AFB_1-treated hamsters killed at 46 weeks. However, 2 hamsters each had a cholangiocellular carcinoma 1 cm in diameter, and microscopic cholangiomas were seen in sections from 6 of the 14 hamster livers. In addition, from the groups of AFB_1-treated hamsters reserved for determination of tumor incidence, 3 that received phenobarbital in the drinking water and 4 that received only tap water died with gross cholangiocellular carcinomas between 28 and 38 weeks. Focal areas of hepatocyte hyperplasia and bile duct proliferation were also observed microscopically in liver sections from AFB_1-treated hamsters, whereas no notable changes were seen in the control livers.

Liver Pathology at 78 Weeks

The 15 surviving hamsters given AFB_1 and the 23 surviving solvent-treated controls were killed at 78 weeks. No gross hepatocellular carcinomas were detected, but microscopic hepatocellular carcinomas were seen in liver sections from 2 AFB_1-treated hamsters, 1 of which was given phenobarbital in the drinking water (fig. 7). The livers from all of the AFB_1-treated hamsters, whether or not they received phenobarbital, exhibited multiple cystic cholangiomas and cholangiofibrosis (fig. 8); 30% of the livers contained hard, white masses that were diagnosed as cholangiocellular carcinomas (figs. 9, 10). Another 3 AFB_1-treated hamsters from these groups died with gross cholangiocellular carcinomas and microscopic cholangiomas between 46 and 52 weeks

Thus the tumor incidence (table 2) for the hamsters includes those that died before 78 weeks and those killed at the termination of the experiment. The mean survival times for the AFB_1-treated hamsters that survived at least 24 weeks were 64 weeks for hamsters given subsequent treatment with phenobarbital and 66 weeks for hamsters not given subsequent phenobarbital treatment. Hamsters given only the vehicle, with or without subsequent phenobarbital treatment, did not develop grossly or microscopically notable hepatic abnormalities. For the control hamsters that survived at least 24 weeks, the mean survival times were 67 or 70 weeks, respectively, for those that did or did not receive phenobarbital.

Three cholangiocarcinomas from the AFB_1-treated hamsters (2 from animals given phenobarbital and 1 from a nonphenobarbital-treated hamster) were each examined with histochemical stains. Each of these carcinomas was ATPase-deficient, Glc-6-Pase-deficient, and GGT-positive. Sections of nontumor hepatic tissue from each of these 3 hamsters and from 1 other AFB_1-treated hamster, without phenobarbital treatment, contained five to ten ATPase-deficient focus transections of hepatic cells per 2- to 3-cm^2 tissue section (fig. 11). These focus transections in the nonneoplastic tissue were not detectable in consecutive sections stained for Glc-6-Pase or GGT or with H & E (fig. 12). The number of ATPase-deficient foci per liver could not be estimated (*20, 21*), since the contribution to the liver weight of numerous hepatic cysts was unknown. Liver sections taken at 78 weeks from 8 hamsters that received only the vehicle (DMSO-trioctanoin), with or without subsequent phenobarbital administration, did not contain any focus transections of hepatic cells that were detectable with the histochemical stains used.

Other Pathology

Only limited study of other tissues was made, since the major focus of this study was a comparison of hepatic tumor development. However, the harderian glands were examined in view of the earlier report of the occurrence of adenomas in these glands in AFB_1-treated hamsters (*11*). Focal glandular atrophy and focal pigmentation of the glands were observed in 2 of 6 rats killed at the termination of the AFB_1 treatments at 6 weeks. No histologic changes were observed in the harderian glands from hamsters at 6 weeks or in any of the rats or hamsters examined at later times up to 78 weeks. However, at 78 weeks 5 of 6 or 6 of 9, respectively, of the AFB_1-treated hamsters that were or were not given phenobarbital had microscopic adenomas of the harderian gland. Similarly, for the vehicle-treated controls the incidences were 3 of 9 or 6 of 14, respectively, for the hamsters that did or did not receive phenobarbital. Harderian gland adenomas were not observed in any of the rats.

The kidneys of the hamsters that received AFB_1 and of the controls showed varying degrees of nephritis with interstitial fibrosis and chronic inflammation, tubular dilatation, cast formation, and occasional hyperplasia. A renal cell carcinoma was found in 1 AFB_1-treated hamster at 78 weeks.

DISCUSSION

These data confirm previous impressions (*9, 11*) that livers of Syrian golden hamsters are much less susceptible than those of rats to the toxic and carcinogenic effects of AFB_1. This finding is consistent with the lower levels of macromolecule-bound AFB_1 residues in the livers of AFB_1-treated hamsters as compared to those of AFB_1-treated rats [(8); Moore MM, Miller EC, Miller JA: Unpublished data]. Both findings are in marked contrast to the severalfold greater capacity of NADPH-fortified hamster liver microsomes, as compared to those of rat liver, to metabolize AFB_1 to the apparent ultimate carcinogen AFB_1-2,3-oxide in vitro (*5–7*). The livers of both species contain glutathione *S*-

transferase activity that forms a conjugate from an AFB$_1$ metabolite, presumably the 2,3-oxide (*25, 26*). Differences in the level of this enzyme or of other metabolizing systems may be one of the factors responsible for the very different susceptibilities of rat and hamster livers to AFB$_1$.

The hepatotoxic and carcinogenic effects of AFB$_1$ in the rat were directed primarily toward the parenchymal cells, as evidenced by the formation of foci of parenchymal cells with altered histochemical staining properties and the development of neoplastic nodules and hepatocellular carcinomas. Although cholangiocellular carcinomas were rare, many hepatocellular carcinomas contained cholangiocellular components, especially at the termination of the experiment for those rats that also received phenobarbital. By contrast, the bile duct cells appeared to be the primary target in hamster livers, since essentially the only neoplasms observed were cholangiomas and cholangiocellular carcinomas that arose late in the experiment. Thus the differences in the susceptibilities of rat and hamster bile duct cells to AFB$_1$ appear to be relatively small as compared to those of their hepatic parenchymal cells.

Since phenobarbital promotes the formation of hepatocellular carcinomas in rats when it is given subsequent to minimal doses of a variety of carcinogens, including 2-acetylaminofluorene, diethylnitrosamine, and certain aminoazo dyes (*14, 27–29*), it was anticipated that phenobarbital might facilitate hepatic tumor induction in the hamster. Whether the negative result that was observed reflects only the strong refractoriness of the hamster hepatic parenchymal cells to the initiation of carcinogenesis by AFB$_1$ or also a lack of promoting activity of phenobarbital in hamsters requires further investigation. Phenobarbital administration to rats appeared to promote the formation of carcinomas that contained cholangiocellular elements. The lack of effect of phenobarbital on the incidence of carcinomas of parenchymal cell origin in rats is readily explicable by the massive dose of AFB$_1$ administered to these animals.

As noted in Herrold's experiment (*11*), a number of the AFB$_1$-treated hamsters developed adenomas of the harderian gland. Although Herrold did not find these adenomas in any of her control animals, these tumors did occur in some of our control hamsters and thus cannot be ascribed to the action of AFB$_1$. Adenomas of the harderian gland have been found in untreated hamsters studied in other laboratories (*30–32*), but the incidences were much lower (≈2%) than those observed in this experiment.

L-Histidinol Protection Against Cytotoxic Action of Cytosine Arabinoside and 5-Fluorouracil in Cultured Mouse Spleen Cells[1,2]

Robert C. Warrington[3,4] *and* **Wei D. Fang**[3,5]

ABSTRACT—The effects of L-histidinol, a structural analog of the essential amino acid L-histidine, on the proliferative responses and anticancer drug vulnerability of cultured spleen cells from male C57BL/6J mice exposed to optimal mitogenic doses of concanavalin A (Con A) or *E. coli* lipopolysaccharide (LPS) were investigated. By means of tritiated thymidine ([^{3}H]dThd) incorporation into acid-insoluble material as the criterion for proliferation, L-histidinol was shown to provide a dose-dependent inhibition of mitogenic responses elicited by Con A and LPS. Total (apparent) inhibition was provided by 1-m*M* concentrations of the analog and, at this concentration, [^{3}H]dThd incorporation was totally reversible even after 72 hours of sustained exposure. Simultaneous addition of L-histidinol and either of the mitogens provide a G_0-like arrest for 24 hours. Thereafter, the cells appeared to begin slow cell cycle transit but did not traverse the G_1/S boundary within 96 hours of incubation. These responses of cultured murine lymphocytes to L-histidinol provided dramatic and extended protection from the cell cycle phase-specific drug cytosine arabinoside and dramatic but transient protection from the cell cycle-specific drug 5-fluorouracil. In principle, these findings extend the L-histidinol anticancer drug approach for improving the therapeutic index of antineoplastic agents, not only to both *cycle-* and *phase-specific* drugs, but also to primary cells of myeloid origin.—JNCI 1982; 68:279–286.

The failure of anticancer drugs to act specifically against malignant cells in vivo represents a major weakness in the armamentarium of cancer treatment (*1*). Many anticancer drugs act against actively proliferating cells, regardless of their status, with resultant toxicities for non-malignant cells of the myelopoietic, gastrointestinal and epidermal tissues. One means of improving significantly the therapeutic index of several classes of currently used anticancer agents would be to reduce, selectively, the number of normal cells in cycle, while not altering the proliferative status of the malignant cell population. A priori, such an approach would increase the specificity of cytotoxic drugs, allow more aggressive treatment regimens, and reduce the deleterious side-effects of chemotherapeutic agents. One means of approaching this goal is to exploit the different growth properties of normal and neoplastic cells. This idea, first proposed in 1974 (*2*) and demonstrated in principle independently by Pardee and James (*3*) and O'Neill (*4*) in 1975, has been endorsed by others subsequently (*5–9*). The assumption inherent in these studies is that appropriate manipulation of the differences in growth responses of normal and neoplastic cells may be a means of conferring specificity upon cell cycle phase-specific drugs in vivo. Unfortunately, many of the reagents employed to date possess too high an inherent toxicity for in vivo applicability (*4, 10, 11*). Nevertheless, if an effective and nontoxic means of evoking differential proliferative responses from normal and neoplastic cell populations in the in vivo situation can be devised, such an approach could offer an improvement for cancer chemotherapy.

Studies from this laboratory (*12–14*) suggest that L-histidinol, a structural analog of the essential amino acid L-histidine, possesses a number of the properties required of an agent capable of enchancing the therapeutic index of anticancer drugs in vivo. L-Histidinol arrests reversibly the growth of a number of cells with normal phenotype and confers total protection from otherwise lethal doses of S-phase drugs. In contrast, the analog does not similarly arrest cell cycle transit of some tumorigenic cell lines and, consequently, does not diminish the susceptibility of these cells to S-phase drugs. In an on-going study, for example, the differential growth response elicited by L-histidinol from the normal/transformed CHO cell pair LR73/TR3 can provide an increase in the therapeutic index of Ara C in excess of 3×10^5 (Warrington RC, Fang WD: In preparation). Among the normal cells shown to be protected from S-phase drugs by histidinol are Balb/3T3 (*12*), LR73, low passage human foreskin fibroblasts (*14*), and 3T3 (*15*). Transformed lines tested to date include mouse L-cells, Balb/3T12, SV101, SVA31 (*15*), TR3, and a rat mammary adenocarcinoma, R13762 (Warrington RC: Unpublished observations).

In this study we extend our investigations of the effects of L-histidinol on proliferative responses and on cytotoxic drug vulnerability to primary cultures of mouse spleen cells. We demonstrate that histidinol not only inhibits the proliferative responses elicited by the mitogens Con A and LPS but also provides significant protection upon these cells from the cytotoxic action of the cell cycle phase-specific drug Ara C as well as the cell cycle-specific drug FUra.

ABBREVIATIONS USED: Ara C=cytosine arabinoside; Con A=concanavalin A; FBS=fetal bovine serum; FUra=5-fluorouracil; [^{3}H]dThd=tritiated thymidine; LPS=lipopolysaccharide.

MATERIALS AND METHODS

L-Histidinol was purchased from Aldrich Chemical Company, Milwaukee, Wis., Con A from Pharmacia, Piscataway, N. J., LPS W (*E. coli*) from Difco Laboratories, Detroit, Mich., and [*methyl*-^{3}H]dThd (6.7 Ci/mmol) from New England Nuclear Corp., Boston, Mass. Mice (20–25 grams body weight) were C57BL/6J males, bred and maintained in the Department of Microbiology, University of Saskatchewan animal facility. FUra was a product of Hoffmann-La Roche Inc., Nutley, N. J., and Ara C was a product of the Upjohn Co., Kalamazoo, Mich.

An appropriate number of C57BL/6J male mice were killed by ether anesthesia and subsequent cervical dislocation. Spleens were removed aseptically and forced gently through a sterile 64-mesh stainless steel screen. The resultant cell suspensions were swirled and pelleted (1,000 rpm, 15 minutes) three times from RMPI 1640 medium supplemented with 5% (vol/vol) FBS. Cell suspensions (0.1 ml, 3 × 10^6/ml) were made up in RPMI 1640+5% FBS, placed in Linbro tissue culture plates, and incubated in a humidified CO_2 incubator (5% CO_2, 37°C). "Nil" samples received no mitogens, whereas the mitogens Con A, 1 µg/ml, LPS, 100 µg/ml, were used at concentrations providing maximal incorporation of [^{3}H]dThd into acid-insoluble material after 48 hours of incubation. Each well was brought to a final volume of 0.2 ml by appropriate additions then 1 µCi [*methyl*-^{3}H]dThd was added. After 6 more hours of incubation (incorporation was shown to be linear over 8 hours), the cells were collected and washed onto filter paper by a semiautomated cell harvester. The filters were dried, placed in vials containing 6 ml scintillation fluid, and the radioactivity (incorporated into acid-insoluble material) was determined. For protein synthesis, [^{3}H]leucine was used in place of [^{3}H]dThd. Each data point represents the average incorporation of four replica wells. Where indicated, bulk (1.0 ml) cultures that had been exposed to various reagents were transferred to sterile siliconized tubes and centrifuged. The cells were washed by three successive resuspension–pelleting cycles. The washed cells were then resuspended in an appropriately reconstituted medium, incubated in Linbro wells and exposed to [^{3}H]dThd as above.

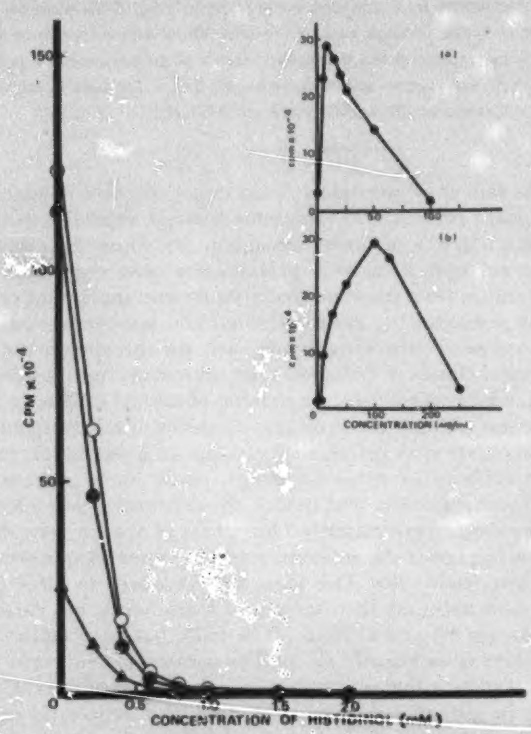
RESULTS

General Assessment of the Effects of L-Histidinol on DNA and Protein Biosynthesis in Cultured Spleen Cells

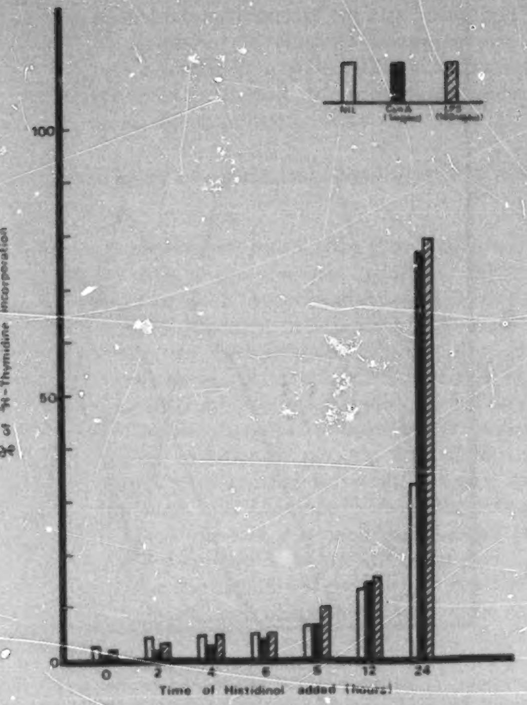
Initial characterizations of the C57 spleen culture system employed in this study included an evaluation of the concentrations of the mitogens Con A and LPS providing maximal incorporation of [^{3}H]dThd into acid-insoluble material, and an assessment of the duration of the linearity of isotope incorporation under optimized conditions. The dose responses of the cells to Con A and LPS, scored by a 6-hour exposure to [^{3}H]dThd after 48 hours of incubation in mitogens, are shown in the insets of text-figure 1. Incorporation after 24 hours of incubation with these mitogens gave qualitatively identical dose responses, although the total incorporation at 24 hours was typically 80–90% of that observed after the 48-hour exposure. Pulse experiments verified that label incorporation was linear for up to 8 hours (not shown) under optimized conditions. This argues that isotope availability is not a rate-limiting factor for the 6-hour pulse period used in all subsequent studies.

The effects of L-histidinol on proliferative responses were assessed initially by examining incorporation in cultures incubated for 24 hours with either no additions (nil) or optimal concentrations of Con A and LPS. In this instance, cultures received simultaneously various concentrations of the analog. Text-figure 1 shows that L-histidinol, added at the time of mitogen addition, provides a dose-dependent inhibition of [^{3}H]dThd incorporation which is qualitatively identical in Con A- and LPS-supplemented cultures, as well as nil cultures. Total inhibition of incorporation, in all cases, was obtained by 1 m*M* L-histidinol.

The time dependency of histidinol inhibition of proliferative responses is documented in text-figure 2. As is the case in most cells exiting quiescence or G_0 (*16*), cultured lymphocytes show a quasi-synchronous proliferative response on exposure to mitogens (*16, 17*). Murine lymphocytes in culture traverse the G_0/G_1 boundary between 3 and 6 hours after mitogen exposure (*18*) and cross the G_1/S boundary approximately 20 hours after stimulation (*18*). Text-figure 2 indicates that L-histidinol inhibits the proliferative re-



TEXT-FIGURE 1.—*Inset*: Dose dependence of Con A (a) and LPS (b) on [^{3}H]dThd incorporation into acid-insoluble material (hereafter, this will be referred to as the less qualified term DNA synthesis). Text-fig.: Inhibition of DNA synthesis by L-histidinol. Cultures were treated with 1 µg Con A/ml (●), 100 µg LPS/ml (○), or no additions (▲) and, at the same time, with the noted concentrations (final) of L-histidinol. After 24 hr of incubation, DNA synthesis was determined as for the inset.



TEXT-FIGURE 2.—Time dependence of the inhibition of DNA synthesis by L-histidinol. Taking the zero time as the time of mitogen addition, at zero time and various intervals thereafter, L-histidinol (1 m*M*) was added to nil-, Con A-, or LPS-treated cells. At 24 hr, DNA synthesis was determined and scored relative to the incorporation observed in cultures not receiving L-histidinol (100%).

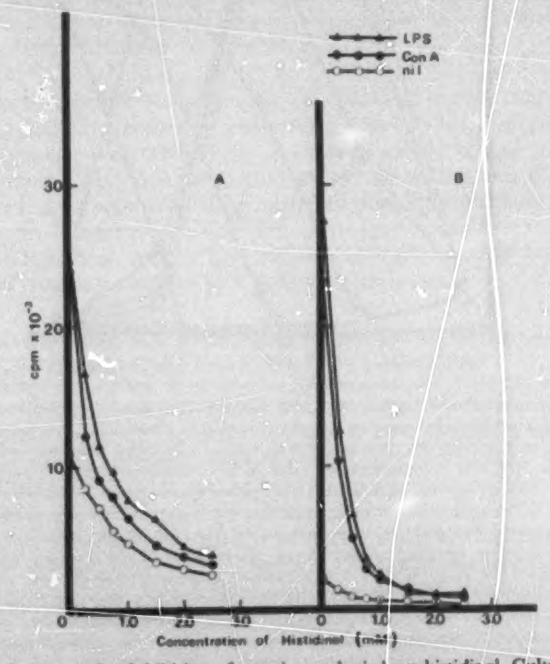
sponses of murine spleen cells maximally if added to G_0 cells, that inhibition diminishes as the drug is added to G_0/G_1 transitting and G_1-committed cells, and that minimal inhibition ensues in S-phase committed cells.

The major and initial effect of L-histidinol on eukaryotic cells is a competitive inhibition of histidyl-tRNA synthetase (*19*). This results in a dramatic elevation of the deacylated form of $\mathrm{tRNA^{His}}$ which, in turn, causes not only an abrupt inhibition of protein biosynthesis (*19, 20*) but also a number of alterations of cellular physiology. These include a profound and specific reduction in rRNA production (*20*) and diminished uptake of various nutrients (*21*), effects collectively termed as negative pleiotypic response (*22*). To establish that L-histidinol was inhibiting protein biosynthesis in spleen cells, the effects of the analog on [^{3}H]leucine incorporation into acid-insoluble material were examined at both early (0–5 hours) and late (17–22 hours) times relative to the time of mitogen addition. Text-figure 3 demonstrates that L-histidinol provided a dose-dependent inhibition of leucine into acid-insoluble material. However, cells treated with L-histidinol early appeared somewhat less inhibited than cells which are assumed to be at or beyond the G_1/S boundary (17–22 hours). Although the significance of this observation is not clear, it does argue that the apparent inability of the analog to inhibit [^{3}H]dThd incorporation in G_1 and S-phase cells is not simply a result of an inability of histidinol to inhibit protein biosynthesis in committed spleen cells.

Histidine Reversal of the Histidinol-Mediated Inhibition of Proliferative Responses of Con A- and LPS-Treated Spleen Cells

Having verified that L-histidinol provided total inhibition of mitogenic responses for 24 hours (text-fig. 1), it was of interest to examine further aspects of its antiproliferative effects. These aspects included an evaluation of the duration of the inhibition, an assessment of whether the inhibition was reversible and, if so, an investigation of alterations in the kinetics of reversal as a function of the duration of incubation. These objectives were examined by preparing cultures treated with either Con A or LPS as well as 1 m*M* L-histidinol. At daily intervals, such cultures were released from the histidinol-mediated proliferative arrest by the addition of excess L-histidine and pulsed with [^{3}H]dThd immediately after reversal and at 24-hour intervals thereafter. One distinct advantage of L-histidinol as an antiproliferative agent is that its effects can be reversed simply by supplementing the treated cultures with excess L-histidine. Since histidinol exerts its effects by a competitive inhibitory mode, the inhibitor itself may be competed against effectively by providing excess histidine (*19, 20*). Therefore, the release of cultures from the histidinol block was achieved by adding L-histidine to the appropriate cultures. The results of these experiments are presented in text-figures 4 and 5.

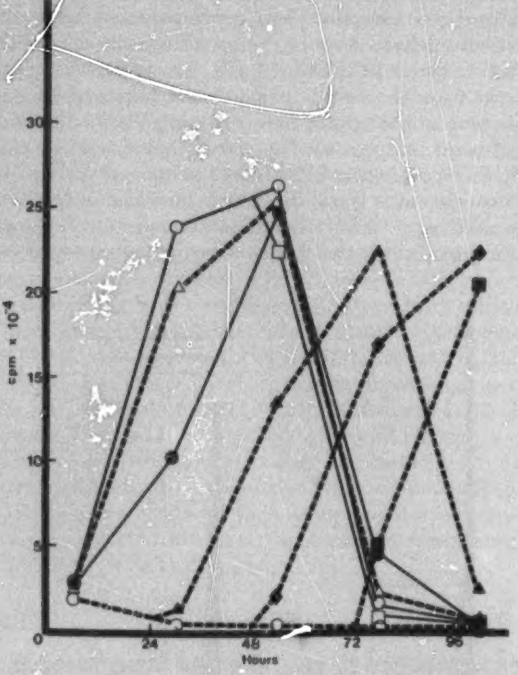
Neither Con A- nor LPS-treated cultures reveal any spontaneous recovery from the block to dThd incorporation mediated by 1 m*M* L-histidinol for up to 96 hours of incubation. That such cultures were incubated continuously



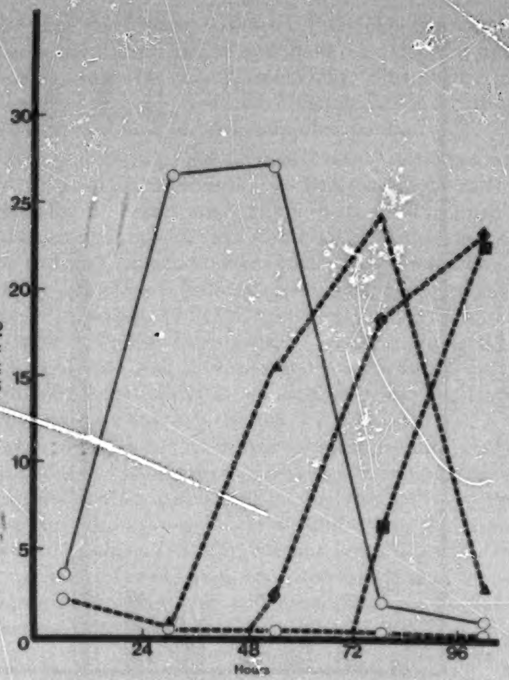
TEXT-FIGURE 3.—Inhibition of protein synthesis by L-histidinol. Cultures supplemented with Con A (●), LPS (▲), or no mitogen (○) were treated with 1 m*M* L-histidinol and 1 μCi [^{3}H]leucine/ml at 0 (A) or 17 hr (B). After 5 hr of incubation, the incorporation of [^{3}H]leucine into acid-insoluble material was determined.

best copy available

in optimal concentrations of the mitogens Con A and LPS, attests to the substantial and long-term effectiveness of histidinol as an antiproliferative agent. Mitogen-treated cultures not receiving L-histidinol showed substantial DNA synthesis for 48 hours with a drastic reduction by 72 hours. Significant restoration of the capacity for [^{3}H]dThd incorporation was observed in L-histidinol-treated cultures supplemented with histidine, even after 3 days of continuous treatment. This observation demonstrates that the L-histidinol-mediated inhibition of proliferative responses is one that is characterized by reversibility. Although the overall apparent rates and maximum levels of incorporation in released cultures are comparable to those observed in the mitogen-treated controls, it is clear that as the incubation continues prior to reversal, the kinetics of incorporation of [^{3}H]dThd change in a consistent manner. In both Con A- and LPS-treated cultures, the level of incorporation observed in the pulse period given immediately after reversal with histidine increases with incubation time. Another trend, which appears to be correlated with the former pattern, is a tendency for cultures held longer in histidinol prior to reversal, to reach maximal apparent rates of incorporation in shorter and shorter reversal periods. Both of these observations suggest, but by no means prove, that histidinol provides a transient G_0 arrest. The transience of the block is presumably a result of chronic mitogenic stimulus that allows the cells to exit slowly from G_0 and to approach but not traverse the G_1/S boundary. The latter point is suggested by the lack of incorporation in histidinol-treated cells not subjected to reversal. These interpretations are further substantiated by the anticancer drug experiments described below.



TEXT-FIGURE 4.—Recovery of DNA synthesis by the addition of L-histidine to L-histidinol–Con A-treated cells. Release from the L-histidinol-mediated proliferative arrest in Con A–L-histidinol-treated cells, 1 µg/ml and 1 m*M*, respectively, was achieved by adding L-histidine dihydrochloride (2 m*M*). For cultures released after 24 hr of exposure to Con A and L-histidinol, ▲- - -▲, replica wells were pulsed from 0–6, 24–30, 48–54, and 72–78 hr relative to the time of addition of L-histidine. Similarly, cultures released after 48 hr, ◆- - -◆, were pulsed from 0–6, 24–30, and 48–54 hr relative to the time of addition of L-histidine. Likewise, cultures incubated for 72 hr in Con A (L-histidinol) prior to release, ■- - -■, were pulsed from 0–6 and 24–30 hr relative to the time of L-histidine addition. Subsequent experiments (not shown) employing L-histidine, rather than L-histidine dihydrochloride, showed an absence of the minor perturbation of DNA synthesis observed here for cultures receiving Con A, L-histidinol, and L-histidine △- - -△. Hence, all subsequent reversal experiments employed L-histidine. ○——○=Con A; ●——●=Con A+L-histidinol+L-histidine; □——□=L-histidine added at 48 hr; ○- - -○=Con A+L-histidinol.



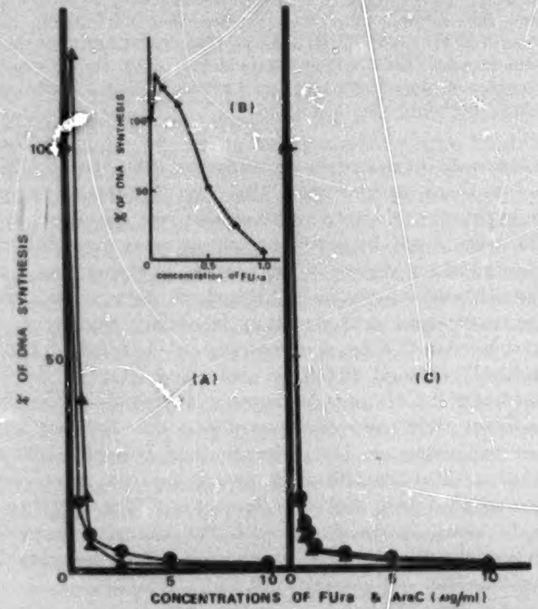
TEXT-FIGURE 5.—Recovery of DNA synthesis by the addition of L-histidine to L-histidinol–LPS-treated cells. Release from the L-histidinol-mediated inhibition of DNA synthesis in LPS–L-histidinol-treated cells, 100 µg/ml and 1 m*M*, respectively, was achieved by adding 2 m*M* L-histidine at 24 (▲), 48 (◆), or 72 (■) hr. The recovery of DNA-synthetic capacity was determined as in text-fig. 4. ○——○=LPS; ○- - -○=LPS+L-histidinol.

Toxicity of Ara C and FUra to Spleen Cells

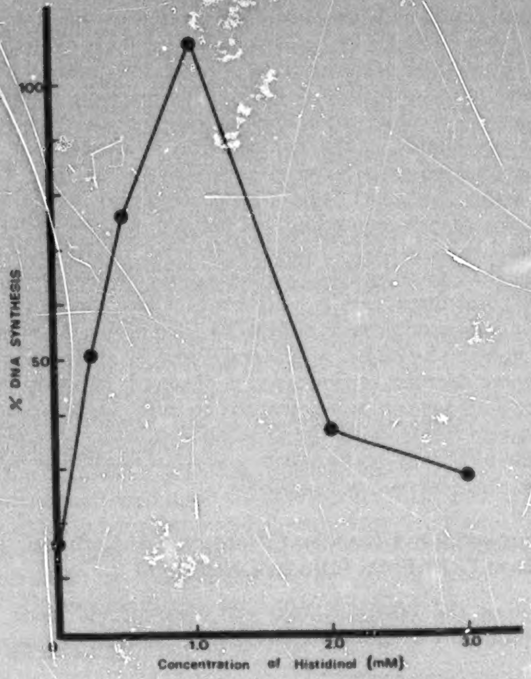
To assess the possibility that the L-histidinol-mediated proliferative arrest of spleen cells would confer protection from cytotoxic action of the cell cycle phase-specific drug Ara C and the cell cycle-specific drug FUra (*23*), it was necessary to evaluate the inherent toxicity of these drugs. Text-figure 6 demonstrates the dose dependency of inhibition of [^{3}H]dThd incorporation by these drugs in Con A- and LPS-treated cultures. The cells were exposed to various concentrations of the drugs for 24 hours and residual DNA-synthetic capacity was scored without removal of the cytotoxic drug. As will be shown below, assessment of residual DNA-synthetic capacity without removal of the drugs provides a substantial overestimate of toxicity. Although low levels of FUra appeared to enhance incorporation, this response may be interpreted as reflecting a perturbation in the specific activity of the thymidine triphosphate precursors rather than an actual stimulatory effect.

Dose Dependency of L-Histidinol-Mediated Protection From Ara C

The previous experiment established that 5 μg Ara C/ml was sufficiently toxic to provide total (apparent) inhibition of [^{3}H]dThd incorporation. Accordingly, Con A-treated cells were given varying doses of L-histidinol and 5 μg Ara C/ml for 24 hours. To score for putative protection, it was necessary to wash these cultures to eliminate Ara C. To facilitate this essential manipulation, bulk (1.0 ml) cultures were prepared and incubated after appropriate additions. At the end of the incubation period, the cultures were transferred to sterile, siliconized tubes and washed as described in "Materials and Methods." The cells were then resuspended in medium and dispersed into Linbro plates (0.2 ml/well) and processed as before. In text-figure 7, the residual DNA-synthetic capacity of the cultures as a function of L-histidinol concentration is shown scored relative to Con A-treated control cultures similarly manipulated. In contrast to the former experiment, wherein the Ara C was not removed prior to assessment, this protocol reveals that Ara C and Con A-treated cells retain, after 24-hour exposure, approximately 15% of the capacity of control cells to incorporate [^{3}H]dThd. The addition of L-histidinol provides a dramatic protective effect, which is dose-dependent up to 1 m*M*. The latter concentration provided total apparent protection from Ara C. The addition of higher concentrations of the analog results in a decline of protection.



TEXT-FIGURE 6.—Inhibition of DNA synthesis in Con A- and LPS-treated lymphocytes by Ara C and FUra. A) Spleen cells received 1 μg Con A/ml and the noted concentrations of Ara C (●) or FUra (▲). After 24 hr, DNA-synthetic capacity was determined without prior removal of drugs and expressed as a percentage of DNA synthesis in cells receiving only Con A (100%) (concentration terms 1, 5, and 10 μg/ml for Ara C and FUra correspond to 4.1, 20.56, and 41.1 μmol and to 7.69, 38.4, and 76.9 μmol, respectively). B) The experiment was as for A except a larger number of low concentrations of FUra were used. C) Spleen cells received 100 μg LPS/ml and the indicated concentrations of Ara C (●) or FUra (▲). DNA synthesis was scored as in A.



TEXT-FIGURE 7.—Dose dependency of L-histidinol-mediated protection from Ara C. Bulk, 1.0 ml, cultures of spleen cells received 1 μg Con A/ml, 5 μg Ara C/ml, and the noted concentrations of L-histidinol. After 24 hr of incubation, the bulk cultures were washed three consecutive times to remove drugs. The cells were then reincubated with Con A alone for 24 hr and then pulsed for 6 hr with [^{3}H]dThd. The incorporation is plotted as a percentage of a control culture, Con A-treated for 24 hr, followed by [^{3}H]dThd pulse.

Substantial and Prolonged Protection of Cultured C57 Spleen Cells From Ara C by L-Histidinol

The previous experiment verified that 1 m*M* L-histidinol provided total protection to spleen cells treated with an optimum mitogenic dose of Con A and a decidedly toxic level of Ara C. It was of interest to attempt to define the duration of the protective influence over a range of Ara C concentrations. The results of such a study are represented in text-figure 8, wherein residual DNA synthesis is equated operationally with cell survival.[6] For cultures receiving Con

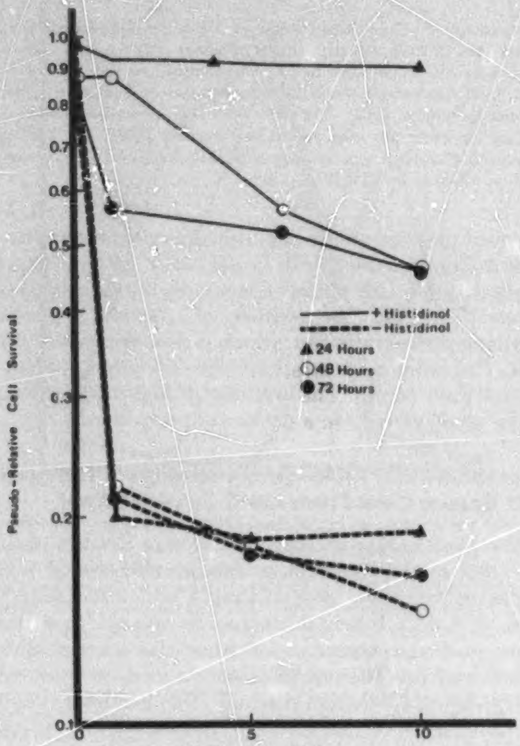
---

[6] Since there is a principled, but not verified, justification of equating residual DNA-synthetic capacity with the more meaningful relative cell survival assay, the data in text-figs. 8 and 9 are presented as *pseudo*-relative cell survival.

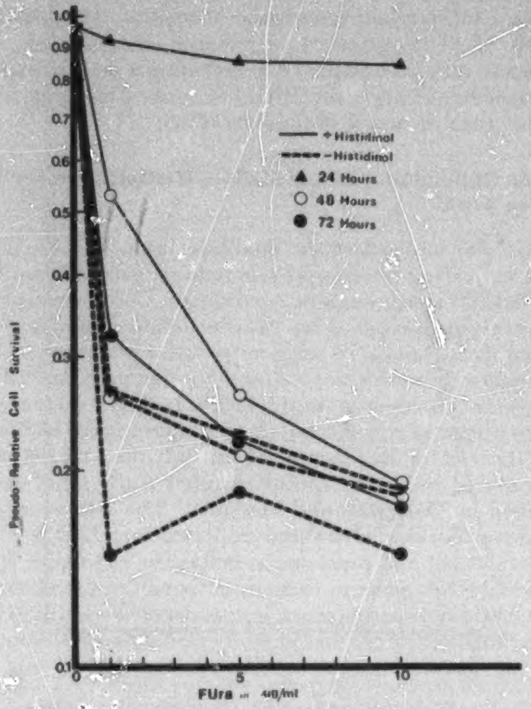
A and Ara C without L-histidinol, it appears that a dose of 1 μg Ara C/ml for 24 hours confers near maximal toxicity. Increased drug concentrations or increased duration of exposure to the drug provide but a rather marginal additional toxicity. This observation may indicate that the majority of cells responding to the mitogen Con A are brought into cycle (and hence rendered vulnerable to this low dose of Ara C) within the initial 24-hour exposure period, with a lesser fraction of cells responding in a delayed manner. However, other modes of Ara C toxicity may be involved (*24*). A different type of response is observed in cultures receiving 1 m*M* L-histidinol, Con A, and Ara C. L-Histidinol provides essentially total protection from all doses of Ara C tested for 24 hours. Thereafter, a moderate dose- and duration-dependent decrease of protection is observed. However, even after 3 days of continuous incubation in the highest concentration of Ara C tested, the histidinol-supplemented cultures retain a DNA-synthetic capacity which is fourfold or higher than that observed in its absence.

Substantial but Transient Protection of Cultured Spleen Cells From FUra by L-Histidinol

Given the generality that cell cycle-specific drugs are useful agents in the chemotherapeutic management of cancer, we were interested in assessing the influence of L-histidinol on FUra, a prototype of this class of anticancer agents. The experimental protocol employed was the same as described for Ara C experiments above, and the results are presented in text-figure 9. For cultures receiving Con A and FUra without L-histidinol, the toxicity patterns are somewhat more dose- and duration-dependent than were observed for Ara C–Con A combinations. Although 1 m*M* L-histidinol provided dramatic protection from all doses of FUra tested for 24 hours of exposure, thereafter we observed significant dose- and duration-dependent decrease in its protective influence. The rather marked difference between the influence of L-histidinol on protection from Ara C, an S-phase specific drug and its influence on FUra, a cell cycle-specific drug, is consistent with the duration-dependent effects of the analog. This observation will be elucidated in the discussion.



TEXT-FIGURE 8.—Protection of Con A-treated cells from Ara C by L-histidinol. Bulk cultures, 1.0 ml, were supplemented with 1 μg Con A/ml, L-histidinol (1 m*M*), or 1, 5, or 10 μg Ara C/ml or 4.1, 20.56, or 41.1 μmol, respectively, as noted. After 1, 2, or 3 days of incubation, the cultures were washed and reincubated with 2 μg Con A/ml for 24 hr and finally pulsed with [^{3}H]dThd for 6 hr.



TEXT-FIGURE 9.—Protection of Con A-treated cells from FUra by L-histidinol. Bulk cultures, 1.0 ml, were supplemented with 1 μg Con A/ml, L-histidinol (1 m*M*), or 1, 5, or 10 μg FUra/ml or 7.69, 38.4, or 76.9 μmol, as noted. After 1, 2, or 3 days of incubation, the cultures were washed, reincubated with 1 μg Con A/ml for 24 hr and finally pulsed with [^{3}H]dThd for 6 hr.

DISCUSSION

The studies presented here establish that murine splenic lymphocytes of both T- and B-cell designation (scored as Con A- and LPS-responsive cells, respectively) are influenced by the histidine analog L-histidinol in a manner reminiscent of that of nonmyeloid normal cells in culture. The histidine analog inhibits B- and T-lymphocyte mitogenic responses, evaluated by the criterion of [^{3}H]dThd incorporation into an acid-soluble form. This inhibition, as seen in nonmyeloid lines, is dependent both upon the dose of the analog as well as upon the time of addition relative to the mitogenic stimulus. A maximal and prolonged inhibition is observed if the analog is added at the time of mitogen addition, whereas delaying the addition of L-histidinol with regard to mitogen addition results in a diminishing suppression of the proliferative response. Cultures receiving both mitogen and L-histidinol simultaneously show total apparent reversibility after 3 days of inhibition, even though these cultures show no spontaneous G_1/S transit for up to 4 days in culture. It is essential that any agent that is contemplated as a means of improving the therapeutic index of anticancer drugs in vivo, should not only provide selective and long-term inhibition of proliferative responses for cells of normal phenotype, but also, it should allow complete reversal following the phase of inhibition. Similar long-term but completely reversible states of proliferative arrest mediated by L-histidinol are observed in other types of cells possessing normal phenotype (*12-15*).

A more critical evaluation of the data presented herein reveals, however, that these myeloid cells are not maintained in a persistent G_0-like state on histidinol treatment, as is the case for their normal but nonmyeloid counterparts (*12-15*). Con A- and LPS-treated murine spleen lymphocytes supplemented with L-histidinol appear to be maintained in a G_0-like state for approximately 24 hours. Thereafter, a cell-cycle progression toward, but not traversing, the G_1/S boundary appears to ensue. The strongest evidence for this interpretation derives from the decay of FUra protection observed in text-figure 9. G_0-exiting cells become vulnerable to FUra, initially, as a result of the marked elevations in RNA synthesis (*23*), which delineates the G_0/G_1 boundary transition (*17*). This macromolecular event begins between 3-6 hours after mitogen treatment of murine lymphocytes (*18*) in the absence of an agent such as L-histidinol. Hence, the vulnerability of analog-treated cells subjected to FUra for periods in excess of 24 hours, combined with the changing kinetics of DNA synthesis following reversal of histidinol treatment (text-figs. 4, 5), suggest that the analog establishes a G_0-sojourn of approximately 24 hours followed thereafter by progression into G_1. We note that essentially identical interpretations were made by Taudou et al. (*26*) in their analysis of the effects of L-histidinol on DNA synthesis in Con A-treated guinea pig lymphocytes. Although these descriptions are consistent with the [^{3}H]dThd incorporation studies and with the duration-toxicity studies using Ara C and FUra, they remain suggestive, nevertheless, pending an investigation by a more definitive approach like the flow cytometric analysis of lymphocyte responses with the use of acridine orange (*17, 25*). Such uncertainties notwithstanding, the inhibition of proliferative responses mediated by L-histidinol is sufficient to provide a dramatic and prolonged protection from the cell-phase specific drug Ara C, as well as a dramatic but transient protection from the cycle-specific drug FUra.

The data presented in this study represent, to our knowledge, the first report that *primary* cells in culture can be protected from anticancer drugs by manipulating their proliferative status using an agent like L-histidinol. Furthermore, we believe that this is also the first documentation that this type of approach can be extended to *cell cycle-specific* anticancer drugs. In principle these observations suggest that a combined histidinol-anticancer drug approach for improving the therapeutic index of anticancer agents may be applicable to a much broader spectrum of drugs than was envisaged originally (*14*). Should the spleen lymphocytes prove to be reminiscent of their more immediate or pluripotent myeloid precursors in terms of their response to L-histidinol, then these results also suggest that the crucial marrow population cells may likewise be provided protection from anticancer drugs by means of the histidinol-anticancer drug approach. This possibility is under investigation currently. We have demonstrated that L-histidinol, given at appropriate schedules in conjunction with a large, single challenge of Ara C, confers substantial protection upon the bone-marrow cell population of intact mice (Warrington RC, Fang WD: Unpublished observation). These observations, based upon the resumption of de novo erythropoiesis and lymphopoiesis following drug treatments, have been confirmed (Warrington RC, Fang WD: Unpublished observation) by experiments relying on the quantitative CFU-C assay for murine bone marrow cells (*27*).

Murine Lymphoma L5178Y Cells Resistant to Purine Antagonists: Differences in Cross-Resistance to Thioguanine-Platinum(II) and Selenoguanine-Platinum(II)[1, 2]

Fumihiko Kanzawa,[3] Mitsuaki Maeda,[4] Takuma Sasaki,[4] Akio Hoshi,[3] *and* Kazuo Kuretani[3]

ABSTRACT—To determine whether the antitumor activities of thioguanine-platinum(II) [TG-Pt(II)] and selenoguanine-platinum(II) [SeG-Pt(II)] are due to direct actions of these compounds or to the actions of their hydrolysis products, studies were made on a purine antagonist-resistant, murine lymphoma L5178Y/MP subline that lacked the anabolic enzyme hypoxanthine-guanine phosphoribosyltransferase necessary for tumor inhibition. The L5178Y/MP subline proved to be highly resistant to both TG-Pt(II) and thioguanine; the resistance ratios to the two compounds were almost identical. The subline showed high resistance to selenoguanine, but the cross-resistance to SeG-Pt(II) was negligible. Whether the compounds exhibit the delayed cytotoxicity characteristic of purine antagonists was also investigated. Delayed cytotoxicity was demonstrated for TG-Pt(II) as well as for thioguanine and other purine antagonists but not for SeG-Pt(II) or *cis*-dichlorodiammineplatinum(II). Experiments on cross-resistance and delayed cytotoxicity showed differences in the cytotoxicities of TG-Pt(II) and SeG-Pt(II): TG-Pt(II) exerted its activity through its hydrolysis product thioguanine, whereas SeG-Pt(II) compound was cytotoxic itself.—JNCI 1982; 68:287–291.

Since the antitumor activity of cisplatin [*cis*-dichlorodiammine-platinum(II)] has proved to be effective as an inhibitor to the growth of several experimental tumors (*1, 2*), considerable efforts have been made towards finding platinum derivatives with better antitumor activity and less toxicity (*3–9*). Previously, several complexes of TG and SeG with platinum, such as TG-Pt(II) and SeG-Pt(II), have been reported to be effective antitumor agents in experimental animals (*10*). They had at least as much cytotoxic activity as the parent compounds but were less toxic to the host. The mechanism of action of these compounds is not fully understood. Their cytotoxicity is thought to be produced by their direct antitumor effects, or through splitting to their respective nucleo-bases (TG or SeG) with subsequent metabolic conversion to their respective nucleotides by HGPRT, a process necessary for tumor inhibition (*11*). Our purpose in this study was to determine which of these two possibilities is correct. To this end, we tested against these compounds the cross-resistance of a cell line lacking HGPRT activity, and, hence, resistant to purine antagonists. We also tested TG-Pt(II) and SeG-Pt(II) for delayed cytotoxicity, which is a characteristic property found in purine antagonists such as MP and TG (*12–14*).

MATERIALS AND METHODS

Chemicals.—TG-Pt(II) and SeG-Pt(II) were prepared as described previously (*10*). Their chemical structures are shown in text-figure 1. SeG was synthesized by the method of Mautner et al. (*11*). Cisplatin and TG, used as reference compounds, were purchased from Strem Co. Ltd., Newburyport, Mass., and Sigma Chemical Co., St. Louis, Mo., respectively. ^{14}C-labeled hypoxanthine (sp act, 55 mCi/mmol) was purchased from the Radiochemical Centre, Amersham, England.

Cell culture.—A clone of murine lymphoma L5178Y cells designated L5178Y/O, sensitive to purine antagonists, was used in the experiments and was also used as the parental line for isolating the MP-resistant cell line. Stock cultures of L5178Y cells were maintained as suspension cultures in exponential growth by three subcultures a week in Fischer's medium (GIBCO, Grand Island, N.Y.) supplemented with 10% horse serum, 100 μg streptomycin/ml and 100 U penicillin/ml in a CO_2 incubator with a humid atmosphere of 5% CO_2 and 95% air as described previously (*15*). Cultures were restarted from frozen stock every 6 weeks.

Evaluation of antitumor action.—We tested the effects of drugs on the proliferation of L5178Y cells in vitro (*16*) by two different methods. First, we evaluated the cytotoxic effect of continuous exposure to drugs on cell proliferation. Duplicate 10-ml cultures, initially containing 2.5×10^4 cells/ml, were incubated in medium with test compounds at various concentrations in capped 50-ml bottles for 48 hours at 37°C. After incubation, cells were counted in either a TOA Microcellcounter CC-108 (TOA Medical Electronics Co., Kobe, Japan) or under a microscope, and the cell proliferation ratio of treated versus control cultures was calculated. Antiproliferating activities were determined as IC_{50} values—the concentrations required for 50% inhibition of cell proliferation of control cultures during incubation for 2 days. The second method was designed to determine delayed cytotoxicity, i.e., the effect of brief exposure to drugs on subsequent cell growth in drug-free medium. Duplicate 20-ml cultures

TG-Pt(II) SeG-Pt(II)

TEXT-FIGURE 1.—Chemical structures of TG-Pt(II) and SeG-Pt(II).

containing 2×10^4 cells/ml were exposed to drugs at various concentrations for 24 hours. The cells were then collected by centrifugation (500×*g*, for 3 min), washed once with warm drug-free medium, resuspended in fresh medium, and incubated for 4 days at 37°C. Samples were taken at regular intervals to determine cell density. After culture for 4 days, the cumulative cell number was calculated by multiplying the cell densities by the dilution factors for each subculture. The cytotoxicity of the drug was expressed as the IC_{99} value—the concentration required for 99% inhibition of cell proliferation in the 4-day period.

Isolation of the resistant cell line.—A cell line resistant to purine antagonists was established by the technique described previously for the selection of the L5178Y/FU subline (*17*). L5178Y cells were submitted to the mutagenic action of 3.0 µ*M* MNNG for 24 hours, then exposed to MP for 24 hours, washed once, and cultured in drug-free medium until cell proliferation resumed. The resulting cells were then exposed to about three times the previous drug concentration. This procedure, termed the drug-treatment episode, was repeated when the cells showed the same proliferation ratio as untreated cultures. After the last episode, the cells were cloned by the soft agar technique using 0.15% Nobel's agar in medium consisting of 9 volumes of Fischer's medium supplemented with 10% horse serum and antibiotics plus 1 volume of conditioned medium.

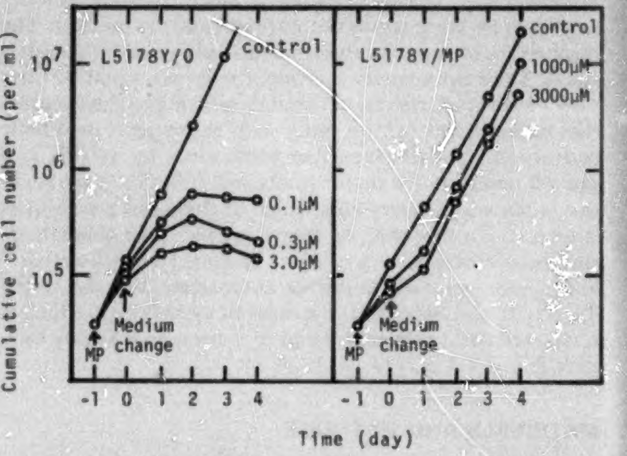
Assay of HGPRT activity.—The ability of sonic extracts of L5178Y cells to convert [8-^{14}C]hypoxanthine to inosinate was assayed by the method of Henderson et al. (*18*). Sonic extracts were prepared by subjecting L5178Y cell suspensions (3×10^7 cells/ml in 50 m*M* Tris-HCl buffer, pH 7.4) to three successive (10 sec) 20-kc bursts of ultrasound with 60-second intervals of cooling at 4°C between bursts. The sonicates were then centrifuged (15,000×*g*, 45 min) and the supernatants were used to assay HGPRT activity. Assay mixtures contained 1 m*M* 5-phosphorylribose-1-pyrophosphate, 1 m*M* magnesium sulfate, 25 m*M* Tris-HCl buffer (pH 7.4), 0.1 m*M* [8-^{14}C]hypoxanthine and sonic extracts of 2×10^5 cells in a final volume of 0.1 ml. After incubation at 37°C, 4 *M* formic acid was added, the mixtures were centrifuged, and an aliquot of the supernatant was chromatographed on cellulose thin-layer chromatography plastic sheets in 5% disodium hydrogen phosphate with appropriate carriers to isolate the reaction product, inosinate. We determined the radioactivities associated with the spots of base, nucleoside and nucleotide on the chromatogram by sectioning the chromatogram and measuring the radioactivity directly in the scintillation fluid.

RESULTS AND DISCUSSION

Isolation and Characterization of MP-Resistant L5178Y Cells

After mutation the L5178Y cells were exposed to 10 µ*M* MP for 24 hours, then passaged for 11 days in drug-free medium. After that, they were cultured for three successive 24-hour episodes in media containing MP at increasing concentrations such as 300, 1,000 and 3,000 µ*M*. Each MP treatment was followed by recovery periods consisting of passage for 5, 8, and 2 days, respectively, in drug-free medium. After the last episode, cells were cloned and 54 clones were picked up at random from individual colonies. Twenty-one of the colonies were discarded because they grew slowly on large-scale culture in normal medium. The other colonies were tested for their ability to grow in medium containing 1,000 µ*M* MP. A clone designated as L5178Y/MP was selected for further studies because of its high resistance to MP. Text-figure 2 shows the proliferation curves of the L5178Y/O parent line and MP-resistant L5178Y/MP subline in drug-free medium 4 days after the treatment with MP at various concentrations for 24 hours. The L5178Y/MP subline was clearly more resistant to MP than the parent line. For example, the L5178Y/O line scarcely grew with 0.3 µ*M* MP (*see* left side of text-fig. 2), whereas with as much as 3,000 µ*M* MP the L5178Y/MP subline grew well (*see* right panel of text-fig. 2). Moreover, the L5178Y/MP subline was at least 1,000-fold more resistant than the L5178Y/O line to continuous exposure to MP (data not shown). This subline also showed cross-resistance to TG and SeG, with ratios of 3,750 and 438, respectively, as shown in table 1. It retained this resistance for at least 6 months during passage in the absence of drugs.

The mechanism of resistance to purine antagonists has



TEXT-FIGURE 2.—Effects of exposure to MP for 24 hr on proliferation of L5178Y/O and L5178Y/MP cells in drug-free medium. Cultures were treated with MP at the indicated concentration for 24 hr. On day 0, cells were transferred to drug-free medium and incubated at 37°C.

TABLE 1.—*Cross-resistance of L5178Y/MP cells to cytotoxicity of test compounds*

Compound	Sensitivity, IC_{50}, μM[a]		Resistance	
	L5178Y/O	L5178Y/MP	Ratio[b]	Degree[c]
Cisplatin	2.9	2.4	0.83	–
TG	0.080	300	3,750	+++
TG-Pt(II)	0.19	740	3,890	+++
SeG	0.40	175	438	++
Seg-Pt(II)	1.40	4.5	3.2	–

[a] Cells were cultured in medium containing test compounds at various concentrations. After 2 days the proliferation ratio was calculated by dividing the No. of cells in the test cultures by those in control cultures. Sensitivity is expressed as the concentration causing 50% inhibition of growth (IC_{50}) determined from the dose-response curve.

[b] Resistance ratio, the ratio of the IC_{50} value of L5178Y/MP cells to that of the L5178Y/O subline, was used as a parameter for the evaluation of cell resistance.

[c] Resistance degree is the resistance ratio expressed on an arbitrary scale: – = ratio of ≤9; + = ratio of 10–99; ++ = ratio of 100–999; +++ = ratio of ≥1,000.

been studied for over a decade. Human tumors become unresponsive to purine antagonists in various ways, including by significant elevation of membrane-bound alkaline phosphatase activity (*19–22*), whereas, in nonhuman systems (*23*, *24*), the most frequent cause of resistance is the absence of the anabolic enzyme, HGPRT, required to convert these antimetabolites to nucleotides, a process necessary for tumor inhibition. Text-figure 3 shows the HGPRT activity of sonic extracts of cultures of L5178Y/O and L5178Y/MP cells. Enzymatic phosphoribosylation of hypoxanthine to inosinate started at the beginning incubation of the sonic extract of L5178Y/O cells, whereas no inosinate was produced by the sonic extract of L5178Y/MP cells under the same conditions. These facts suggested that loss, or marked decrease, of the activity of the anabolic enzyme HGPRT in L5178Y/MP cells contributes to the resistance of these cells to purine antagonists such as MP, TG, and SeG.

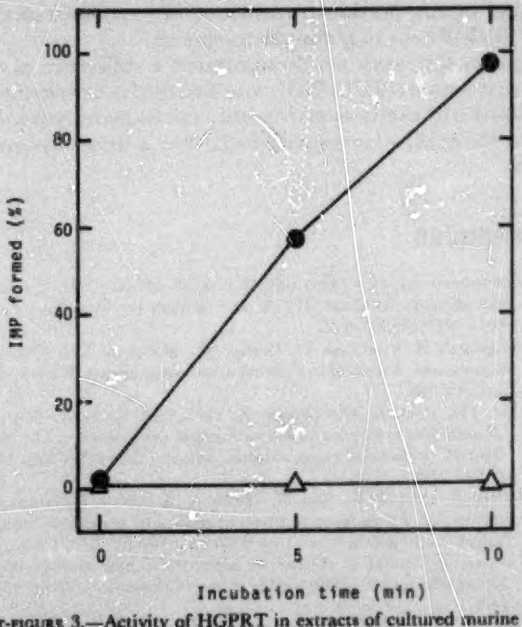
Cross-Resistance of L5178Y/MP to Platinum Complexes

The cytotoxic effects of drugs on the proliferation of the L5178Y/O and L5178Y/MP cells were examined. From the linear log dose-probit plots observed, the IC_{50} values were determined and are shown in table 1. First, as a reference, cisplatin was tested. Cisplatin exhibited almost full activity against the L5178Y/MP subline as well as L5178Y/O parent line indicating that the subline has no cross-resistance to cisplatin. The IC_{50} value of the L5178Y/O line for TG was 0.08 μM and that of the L5178Y/MP subline was 300 μM; that is, the L5178Y/MP subline was about 3,750-fold more resistant to TG than the L5178Y/O line. Further, the IC_{50} value of the L5178Y/MP line for TG-Pt(II) was 740 μM, or 3,890 times greater than that of the sensitive line. Thus the resistance ratio of TG-Pt(II) was almost identical with that for TG. The cross-resistances of the L5178Y/MP subline to SeG and SeG-Pt(II) were also tested under similar conditions. The L5178Y/MP subline exhibited a high resistance ratio, 458, to SeG, but its cross-resistance to SeG-Pt(II) was negligible as shown in table 1.

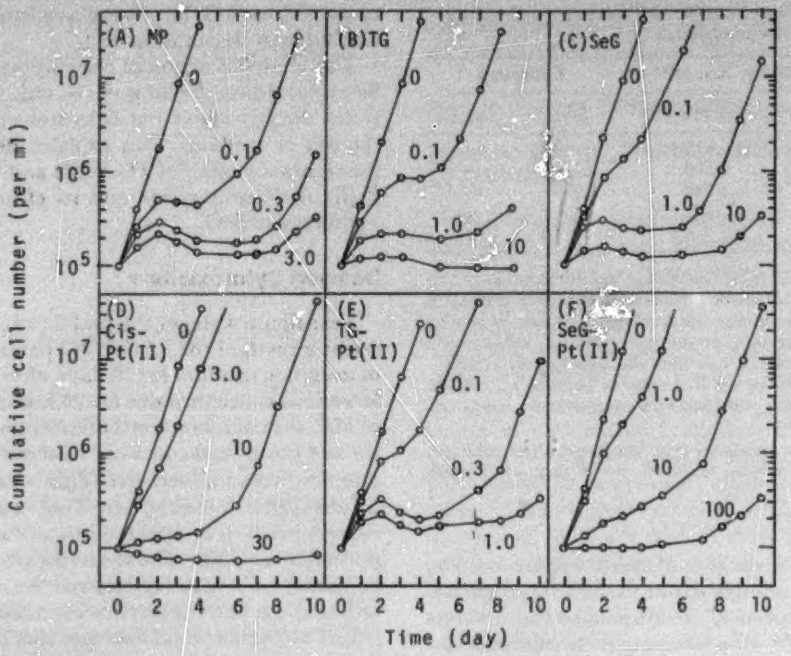
The modes of action of the two platinum complexes can be explained on the basis of the resistance ratios. TG-Pt(II) is not directly active but is hydrolyzed to cytotoxic TG in the cell or medium. This explains the similiarity between the resistance ratios of TG-Pt(II) and TG. Conversely, SeG-Pt(II) itself is cytotoxic and its effect is not the result of hydrolysis to SeG.

Delayed Cytotoxicity

Text-figure 4 shows the proliferation curves of the subsequent growth of the L5178Y/O parent cells when cultured in drug-free medium for 10 days, after treatment with drugs at various concentrations for 24 hours. After brief exposure to MP, the cumulative cell number gradually increased and showed downward concavity at about the time that the cell numbers began to decrease. This behavior pattern, defined as "delayed cytotoxicity" by Tidd et al. (*12*) and Tidd and Paterson (*13*), is a characteristic of the antitumor action of purine antagonists. The delayed cytotoxicity is believed to be caused by a time-lag between the exposure of the tumor cells to drugs and the physical manifestation of drug toxicity (*13*). The phenomenon indicates that cell division continued in the presence of drugs, and that after removal of the drugs one to two doublings still occurred before the anabolism of MP to TG nucleotides, and the incorporation of TG nucleotides into DNA (*25*). In this study, TG and SeG also showed delayed cytotoxicity (text-figs. 4B, 4C). The delayed response of the cells to TG-Pt(II) became apparent when the cells were exposed to the drug at concentrations of 0.3 and



TEXT-FIGURE 3.—Activity of HGPRT in extracts of cultured murine lymphoma L5178Y cells sensitive or resistant to MP. The procedure for enzyme assay is described in the text. (●—●) L5178Y/O; (△—△) L5178Y/MP.



TEXT-FIGURE 4.—Proliferation curves of murine lymphoma L5178Y cells treated with MP (A), TG (B), SeG (C), cisplatin (D), TG-Pt(II) (E), and SeG-Pt(II) (F). Cultures were treated with drugs at the concentrations (*μM*) indicated for 24 hr. On day 1, the culture fluid was replaced by drug-free medium.

1.0 *μM*. Conversely, the response of the cells to identical treatment with SeG-Pt(II) (text-fig. 4F) showed no delayed cytotoxicity, an effect similar to that of cisplatin (text-fig. 4D). The demonstration of delayed cytotoxicity of antitumor activity of TG-Pt(II) but not SeG-Pt(II) confirms the findings of the previous experiment of cross-resistance of L5178Y/MP cells to platinum complexes.

Thus in this work we demonstrated a difference in the cytotoxic actions of TG-Pt(II) and SeG-Pt(II) by two methods. TG-Pt(II) exerts its activity through its hydrolysis product in the cells, whereas SeG-Pt(II) has a direct cytotoxic action.

Production of Kidney Tumors in Rats With Low Dose of Dimethylnitrosamine After Partial Hepatectomy[1]

Ritva P. Evarts,[2] Carolyn A. Brown,[2] *and* Mostafa Hassan Mostafa[3,4,5]

ABSTRACT—The occurrence of kidney tumors in inbred Wistar rats as a result of dimethylnitrosamine (DMN) administration at different intervals after partial hepatectomy was studied. The schedule for DMN administration was determined on the basis of the levels of liver dimethylnitrosamine demethylase (DMN-*d*) at different intervals after the operation. DMN-*d* was 62% of the control values at 24 hours, 72% at 72 hours, and 96% at 92 hours after the operation. At these intervals a single dose of DMN (10 mg/kg body wt) was given to partially hepatectomized animals and to untreated controls. At termination, when the animals were 94 weeks old, no kidney tumors were found in the control animals, whereas 23 of 54 animals (43%) that had been given injections of DMN 24 hours after partial hepatectomy developed kidney tumors. Kidney tumor incidence was 28 or 12%, respectively, when the carcinogen was administered 72 or 92 hours after the operation. The kidney tumor incidence and the activity of liver DMN-*d* were inversely related.—JNCI 1982; 68:223–298.

When administered to animals in small doses during extended time periods, DMN produces liver tumors, whereas one large dose of this carcinogen produces kidney tumors in the surviving animals (*1*). The activity of the microsomal enzyme system that metabolizes DMN, DMN-*d*, is low in the newborn liver, reaches its maximum at puberty, and is again low in adult liver (*2*). This enzyme produces from DMN the ultimate reactive carcinogenic species that form covalent bonds with body macromolecules. Despite the high labeling of liver DNA by DMN after one injection of carcinogen (*3–5*), only kidney tumors are produced (*6*). Thus liver seems to be resistant to tumor production by a single large dose of DMN. When the activity of the microsomal enzyme system is low naturally as in newborn animals (*2, 7*) or when it is lowered by dietary (*8–11*) or chemical means (*12–15*), peripheral tissues, especially kidney, become more sensitive to the carcinogenic action of DMN (*8–14*). Besides removing a large portion of the liver, partial hepatectomy lowers the activity of DMN-*d*, which returns to a normal level after a few days (*16, 17*). In the present experiment we took advantage of this effect of partial hepatectomy on DMN-*d* to investigate the occurrence of kidney tumors in rats as a result of DMN administration at different intervals after partial hepatectomy.

MATERIALS AND METHODS

In the first part of the experiment 64 Wistar inbred female rats (average wt±SD, 135±8.21 g) from Charles River Breeding Laboratories, Wilmington, Mass., were used. Half of these rats were partially hepatectomized according to the procedure of Higgins and Anderson (*18*), with removal of the left lateral and median lobes. The operation was timed such that the subsequent termination of the animals could be performed between 9 and 12 a.m. Four control rats without operation and 4 partially hepatectomized animals were killed at the following intervals after the operation: 6, 13, 24, 32, 48, 72, 92, and 168 hours. Livers were removed, homogenized in 4 volumes of 0.1 *M* potassium phosphate buffer (pH 7.4), and centrifuged for 20 minutes at 9,000×*g*. The supernatant was centrifuged at 105,000×*g* for 1 hour. The microsomal pellet was suspended in 0.1 *M* phosphate buffer and the centrifugation at 105,000×*g* was repeated. DMN-*d* activity was determined as described earlier (*19*). The substrate concentration used was 4 m*M*. Protein was measured by the method of Lowry et al. (*20*). Cytochrome P_{450} was measured by the method of Omura and Sato (*21*) with 91 $mM^{-1}\times cm^{-1}$ as the molecular extinction coefficient for the reduced cytochrome P_{450}–CO complex.

In the second part of the experiment 167 Wistar inbred female rats (average wt±SD, 138±4.66 g) also from Charles River Breeding Laboratories were used. Partial hepatectomy was performed on 116 animals that were divided into 3 groups. DMN (10 mg/kg body wt) was given by ip injection to the first group at 24 hours (61 rats), to the second group at 72 hours (37 rats), and to the third group at 92 hours (18 rats) after the operation. The timing of the operation was such that the animals were given injections between 9 and 12 a.m. Control rats (51) received the same amount of DMN, also by ip injection. The animals were fed Wayne Lab Blox and water ad libitum and their weights were recorded monthly. Animals were killed if moribund; the entire experiment was terminated when the animals were 94 weeks old, and all the animals were necropsied. Kidneys, liver, lungs, stomach, and bladder were examined for evidence of neoplasms. Tissues were fixed in Bouin's solution

and the histologic preparations were stained with hematoxylin and eosin. For microscopic examination each kidney was sectioned sagittally in three or four planes. For statistical analyses the chi-square test was used.

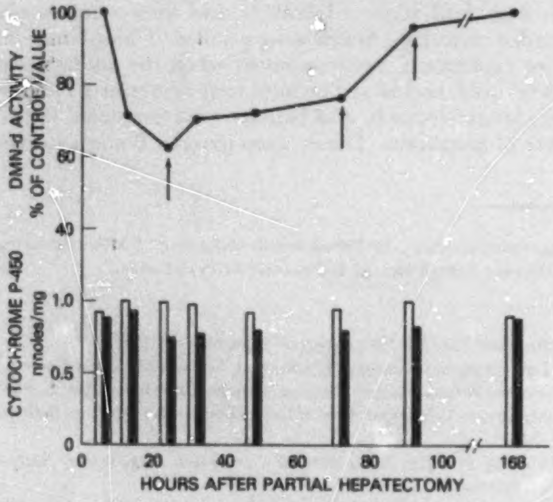
RESULTS

The activity of DMN-*d* was lowest 24 hours after partial hepatectomy and gradually returned to the normal levels in 4–7 days (text-fig. 1). The total amount of cytochrome P_{450} was also lowest 24 hours after the operation, but it remained low several days after the operation. However, in 1 week it had returned to the normal level.

To study the relationship between liver DMN-*d* activity and the incidence of kidney tumors, we selected the 24-, 72-, and 94-hour intervals after partial hepatectomy for administration of DMN. At these intervals the activity of liver DMN-*d* was, respectively, 58, 67, and 89 nmol/hour/mg microsomal protein. The pooled value for control animals was 93 nmol/hour/mg microsomal protein. Table 1 shows the incidence of kidney tumors in the different groups. No kidney tumors were produced among the controls when the same dose of DMN per kilogram body weight was administered, whereas nearly half of the animals that received DMN 24 hours after the partial hepatectomy developed kidney tumors. The tumor incidence was 28% when DMN was administered 72 hours after the partial hepatectomy, whereas in the 92-hour group only 2 of the 17 animals developed renal rumors.

According to Higgins and Anderson (*18*), percentages of restored weights of liver at 24-, 72-, and 92-hour intervals during restoration were 45.3, 70.6, and 74.3% of the controls, respectively, when median and left lateral lobes of the liver were removed at operation. Table 2 shows the restored liver weights calculated from the average liver weights of the control rats killed at the same intervals and the specific and total liver microsomal DMN-*d* activities of the operated rats. When the specific activity of liver DMN-*d* was plotted against the incidence of kidney tumors, an inverse relationship was obtained. When the total DMN-*d* activities of the restored livers 24, 72, and 92 hours after the operation were plotted against the incidence of kidney tumors (text-fig. 2), a similar inverse relationship was obtained.

Macroscopically, most of the kidney tumors were visible beneath the renal capsule. Either they were well demarcated from the adjacent renal parenchyma with a pale cut surface



TEXT-FIGURE 1.—Four control and 4 partially hepatectomized rats were killed 6, 13, 24, 32, 48, 72, 92, and 168 hr after the operation. Liver microsomal DMN-*d* activity is expressed as percentage of the corresponding control values. Cytochrome P_{450} is expressed as nmol/mg microsomal protein. *Open bars* = control rats; *solid bars* = partially hepatectomized rats.

or the whole kidneys seemed to be transformed into large cystic tumors that were partly necrotic and partly filled with brownish fluid. The weight of the necrotic tumors including the kidney varied from 4 to 20 g.

Table 3 shows the distribution of the histologically different renal tumors. The difference between adenomas and adenocarcinomas was difficult to assess. Both tumors were usually well demarcated against the normal kidney parenchyma and both showed an expansive mode of growth. However, adenocarcinomas frequently seemed to be multifocal or bilateral. Cellular pleomorphism, mitotic activity, and focal necrosis were the criteria on which the difference between the adenomas and adenocarcinomas was based. Adenomas were mostly solid with acidophilic or pale-staining cytoplasm (fig. 1). The nuclei were small, round, or oval or vesicular with prominent nucleoli (fig. 2). Mesenchymal tumors were rare. They seemed to infiltrate the kidney parenchyma and extended more deeply into the subcortical area. The tumor cells were small, dark-staining spindle cells (fig. 3).

In addition, cystic lesions lined by eosinophilic or basophilic epithelium were encountered in partially hepatectomized animals but not in the controls (fig. 4). The tissue around the cyst showed distinct morphologic changes.

In the present experiment only a few neoplastic or preneoplastic liver changes were encountered. Fibromas seemed to originate from the incision site in the liver. Only one liver cell tumor was present. However, acidophilic liver cell nodules and basophilic and clear cell areas were present among the operated animals (table 4). No tumor or histologic changes were found in the other tissues examined.

DISCUSSION

The purpose of the present experiment was to assess the importance of active liver DMN metabolism for tumor production in extrahepatic tissue, especially in the kidney. In the past, kidney tumors have been produced by high doses of DMN (up to 40 mg/kg body wt). This dose usually gives about 50% tumor incidence (*10*). To produce kidney tumors with lower doses of DMN, previous workers have used treatments that decrease the activity of DMN-metabolizing enzymes in liver. Either administration of CCl_4, which decreases the amount of cytochrome P_{450} and the activity of DMN-*d* (*13-15*), or administration of high-carbohydrate, low-protein diets, which have similar effects (*22*), has been used to produce kidney tumors with a relatively low dose of DMN. Craddock (*23*) produced a 43% liver tumor incidence and a 71% kidney tumor incidence with a single dose of DMN after partial hepatectomy. In another study dimethylformamide, which lowers the metabolism of DMN, had no effect on liver tumor production of DMN; however, the incidence of kidney tumors was not reported (*24*). In the same study a 33% kidney tumor incidence was produced when 9 mg DMN/kg was given 31 hours after partial hepatectomy. However, one question remains to be answered. Do these treatments affect the kidney as well and thereby increase the susceptibility of the kidney to tumorigenesis by DMN? We tried to approach the question of the importance of active liver metabolism for the peripheral tissue by administering relatively low doses of DMN to the partially hepatectomized rats at appropriate intervals after partial hepatectomy. The timing of the administration was based on determinations of the activity of DMN-*d* at the different intervals after the operation. A similar approach has been used by other workers, but the number of animals used in previous work limited the conclusion that could be drawn (*16*). In our experiment the enzyme activity was lowest 24 hours after the operation and then gradually increased until in 1 week it was back to normal. However, the amount of cytochrome P_{450} remained low for a long time. In our study only 1 of the partially hepatectomized rats developed a hepatocellular neoplasm. There were 2 fibromas and 3 nodules present among these animals.

TABLE 3.—*Distribution of kidney tumors in rats*

Group	Total No. of animals with tumors	No. of adenocarcinomas	No. of adenomas	No. of mesenchymal tumors	No. of cysts
Control	0	0	0	0	0
24 hr	23	7	14	2	2
72 hr	9	2	5	2	1
92 hr	2	0	2	0	1

TABLE 4.—*Distribution of liver cell alterations and tumors in rats*

Group	Hepatoma	Fibroma	Liver cell nodule	Clear cell areas	Basophilic areas
Control	0	0	0	0	0
24 hr	1	1	2	1	3
72 hr	0	1	1	3	5
92 hr	0	0	0	1	0

When the pooled kidneys from control rats and partially hepatectomized rats were analyzed for DMN-*d* activity, no difference in the kidney DMN-*d* activity was found. The value for the control kidneys was 37 nmol/hour/mg microsomal protein and for the operated animals 31 nmol/hour/mg microsomal protein. Thus the change in the kidney DMN-*d* does not seem to play an important part in the production of kidney tumors after partial hepatectomy. However, the determination of DMN-*d* activity when whole kidney is used can be inaccurate because the kidney is composed of anatomically and functionally different parts. The kidney cortex is known to have a drug-metabolizing enzyme system (*25, 26*). This enzyme system can be confined to a relatively small population of renal cells and still exist in concentrations similar to those in hepatocytes (*27*). All the tumors encountered in the kidney were in the cortical area. Large cysts lined with transformed epithelium that formed fold and papillary projections to the lumen of the cysts seemed to be the first step toward tumor production.

Our experiments showed an inverse relationship between the activity of liver DMN-*d* and kidney tumor production. There was also an inverse relationship between the total liver DMN-*d* activity and kidney tumor production (text-fig. 2). Most likely, both the removal of a large portion of the liver and the decrease of the specific activity of the enzyme that metabolizes DMN play an important role in the production of the kidney tumors by DMN. However, many other studies have shown that only a decrease in the specific activity of the liver is enough for tumor production in the kidney (*3, 10, 16*). In addition, alkylation of kidney DNA increased when liver enzyme activity decreased as shown by Swann et al. (*5*) when a protein-free diet was fed to the animals. The kidneys become the target whenever higher doses of DMN reach them due to impairments in the liver mixed-function oxidase system.

Inhibition of Iodinated Nerve Growth Factor Binding by the Suspected Tumor Promoters Saccharin and Cyclamate[1,2]

Douglas N. Ishii, *Ph.D.*[3,4]

ABSTRACT—The strong correlation between tumor-promoting activity and the capacity to inhibit nerve growth factor-induced neurite outgrowth for a number of compounds prompted studies on the suspected bladder tumor promoters saccharin and cyclamate. These artificial sweeteners reversibly inhibited neurite outgrowth and binding of $[^{125}I]$nerve growth factor in embryonic chick sensory ganglia cells. Curves showing the dose-dependent inhibition of response and the dose-dependent inhibition of binding to high affinity sites were closely parallel. The inhibition appeared to be due to a reduction in the affinity rather than to a change in the number of binding sites, as indicated by the extent of reduction in the association rate. These results suggest that alteration of cellular differentiation by tumor promoters may result from interactions with receptor systems that regulate specialized cell functions.—JNCI 1982; 68:299–303.

Certain plant diterpene esters, such as TPA, that are potent tumor promoters in the two-stage mouse skin carcinogenesis system (*1–3*) are reversible inhibitors of neurite outgrowth, while their nonpromoting structural congeners are not (*4, 5*). The suspected bladder tumor promoters saccharin (*6–10*) and cyclamate (*8, 9*) have recently been shown to share this property with the tumor-promoting plant diterpenes (*11*). This inhibitory action is significant, since different chemical classes of promoters often do not show similar effects in a given tissue (*12, 13*). Non-phorbol ester promoters have received scanty attention, but any general mechanism of promoter action must, of course, satisfactorily explain how these other chemical classes of promoters act. This study was conducted to determine whether antagonism of NGF-induced morphologic differentiation in cultured embryonic chick DRG by these artificial sweeteners could be accounted for by inhibition of NGF binding. Little is known of the mechanism of how neurite outgrowth and how the specialized topography of neurons are regulated, although cell shape is of obvious importance to neuronal function. Studies on the mechanism of NGF action may be aided by the availability of antagonists. Reviews on the chemistry of NGF and its effects on the growth and development of the vertebrate nervous system are available (*14–18*). The data are discussed in light of the known effects of tumor promoters on differentiation in other cell systems.

MATERIALS AND METHODS

Chemicals.—Sodium saccharin (S-1002 lot 117C-0154) and sodium cyclamate (C-9131, lot 57C-0157) were purchased from Sigma Chemical Co., St. Louis, Mo. According to the manufacturer, sodium saccharin was synthesized by the Maumee procedure. Sodium cyclamate was more than 99% pure and the content of cyclohexylamine was unknown. Other chemicals were of the best commercially available grades.

Ganglia culture and bioassay.—The detailed procedures for ganglia culture and bioassay are described elsewhere (*4*). DRG from embryonic 7- to 10-day-old white leghorn chick embryos were cultured in RPMI-1640 containing 1 mg BSA/ml and 2 ng NGF/ml on a rattail collagen-coated Microwell plate. The Na^+ concentration and osmolarity of the medium was kept constant by regulation of the NaCl content of the RPMI-1640 medium. The extent of nerve fiber outgrowth was monitored as described in the text-figure legends.

Preparation and iodination of NGF.—NGF was prepared from male mouse saliva (*19, 20*) and purity was confirmed by the presence of a single band on isoelectric focusing (pH 3.5–10) in 7.5% polyacrylamide gels. Purified NGF was iodinated with lactoperoxidase (*21*) and a single band was detected on isoelectric focusing and on sodium dodecyl sulfate gel electrophoresis.

Binding of $[^{125}I]$NGF.—Assay of binding to intact cells obtained from dissociated DRG closely followed procedures described by others (*22*), except that cells ($1\text{–}2\times10^6$/ml) were incubated at 37°C in RPMI-1640 containing 5 mg BSA/ml and $[^{125}I]$NGF. Since Na^+ ions slightly inhibit binding, it is important that Na^+ concentration and total osmolarity be controlled as described above. Incubates were subjected to equilibrium sedimentation for 30 seconds in a Beckman Model 152 Microfuge (Beckman Instruments, Inc., Palo Alto, Calif.), and the cell pellet fraction, and sometimes the supernatant fraction, were assayed for total radioactivity content. Binding to two classes of high affinity sites (*22*) can be distinguished. After incubation for 10 minutes on ice with excess (10 μg/ml) nonradioactive NGF,

binding to the high affinity component (site I) was quantitatively retained. Binding to the lower affinity component (site II) was defined as the difference between total binding and site I binding and was rapidly and quantitatively lost. Nonspecific binding was determined from other incubates containing an excess of 10 μg NGF/ml at the onset and was subtracted from reported values.

RESULTS

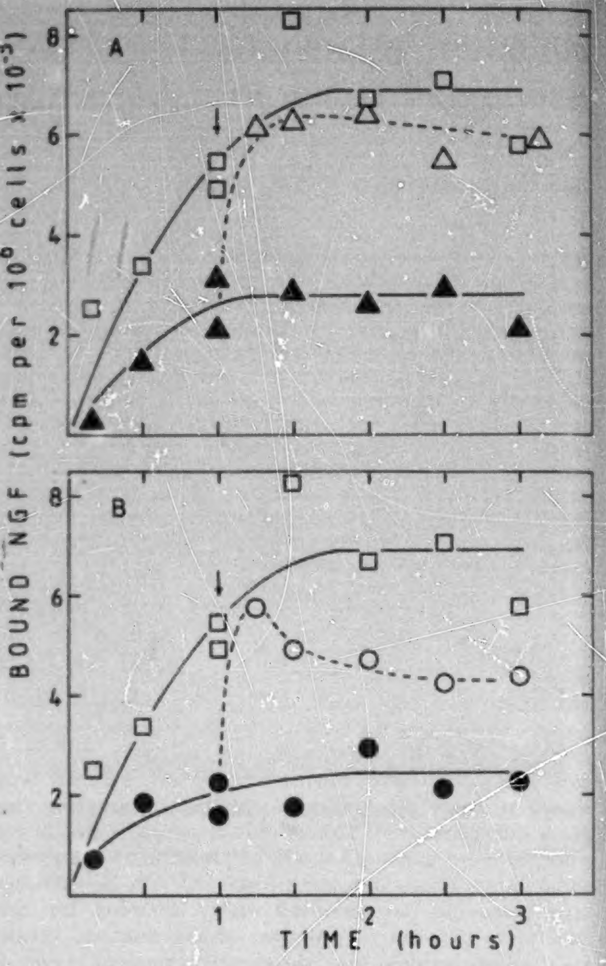
Reversible Effect of Promoters on [^{125}I]NGF-Binding and DRG Response.

The total amount of radioactivity specifically bound to DRG cells incubated with [^{125}I]NGF was inhibited at about the rate of 50% with 50 m*M* sodium saccharin and about 64% with 56 m*M* cyclamate (text-fig. 1). Binding recovered rapidly and completely after the artificial sweeteners were washed out. With cyclamate, however, recovery of binding after washout reached a transient maximum followed by a decline to a plateau level of about 62% of the total binding. These unusual kinetics invite further study. Concentrations of about 50 m*M* of artificial sweeteners cause substantial inhibition of neurite outgrowth in cultured DRG, which is rapidly and completely reversible by washout of the compounds, whereas 50 m*M* glucose or sucrose cause no detectable effect on neurite outgrowth (*11*).

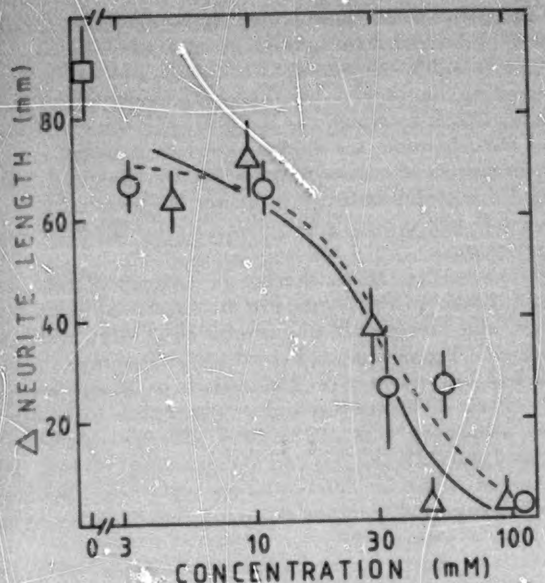
Relationship Between Promoter Concentration, DRG Response, and [^{125}I]NGF Binding.

The effect of various concentrations of saccharin and cyclamate on neurite outgrowth was studied (text-fig. 2). Previously, DRG response was scored (*11*) by the classical semiquantitative bioassay method (*23*). We have chosen an alternative method to detect DRG response, and measured the neurite length. Ganglia were exposed to NGF for 1 day to permit neurites to penetrate the ganglia capsule. Neurite length was measured before and after exposure to artificial sweetener compounds for an additional day. The rate of neurite outgrowth in control cultures appeared linear over 2 days. Neurite length increase was inhibited by saccharin or cyclamate concentrations above 5–10 m*M* (approximately 1–2 mg/ml), and half-maximally by about 25 m*M*. Established neurites were not caused to retract by any drug concentration; other experiments showed that artificial sweeteners decrease the rate of neurite elongation. Half-maximal inhibition of the classical bioassay score was at about 33 m*M* for cyclamate and 50 m*M* for saccharin (*11*). These data correlate reasonably well with effects on inhibition of radioactive NGF binding (text-fig. 3).

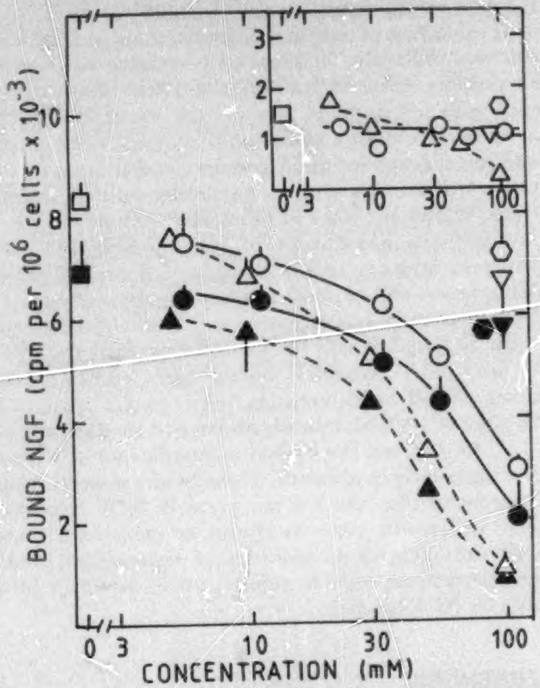
Instead of studying the effect of cyclamate and saccharin concentrations on total binding, I studied the effect on binding to the two high affinity components termed site I ($K_d \cong 2.3 \times 10^{-11}$ *M*) and site II ($K_d \cong 1.7 \times 10^{-9}$ *M*) by Sutter et al. (*22*). NGF binding to site I was inhibited by artificial sweetener concentrations above 5–10 m*M*, and the curves for the dose-dependent inhibition following closely those of the inhibition of neurite outgrowth. Saccharin inhibited NGF binding to site II as well, but in this experiment, cyclamate did not. However, in other experiments, cyclamate could clearly inhibit site II binding. In contrast to artificial sweeteners, high concentrations of glucose and sucrose had little, if any, effect on binding. Since regulation of neurite outgrowth correlates best with NGF binding to site I (*22*), I shall not discuss further the effects on binding to site II here. Significant differences between effects on site I and site II will be presented elsewhere.



TEXT-FIGURE 1.—Time course of saccharin and cyclamate inhibition of total specific [^{125}I]NGF binding to DRG cells, and recovery following washout of sweeteners. Intact cells from dissociated 8-day-old embryonic chick DRG were incubated at 37°C with 5 ng [^{125}I]NGF/ml (sp act, 58 cpm/pg; 2×10^{-10} *M*) alone and with saccharin or cyclamate. At the time shown (*arrow*) incubates were centrifuged and the cells were resuspended in the same initial incubation solutions. Some treated incubates were resuspended in the absence of sweeteners. At various times, aliquots were removed and assayed for total bound radioactivity. Nonspecific binding was estimated from parallel incubates containing excess nonradioactive NGF (10 μg/ml), and values were subtracted from total binding. Panel A: □, control; ▲, plus 50 m*M* sodium saccharin; and △, incubates initially with saccharin followed by washout. Panel B: □, control; ●, 56 m*M* sodium cyclamate added; and ○, incubates initially with cyclamate followed by washout.



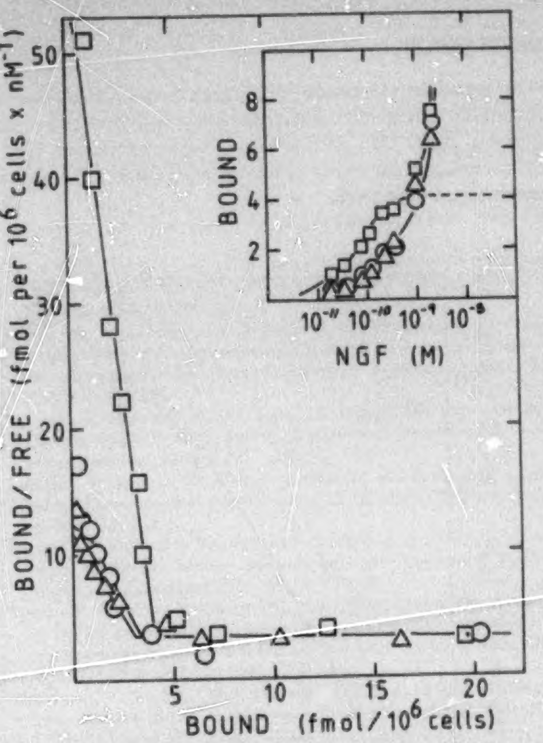
TEXT-FIGURE 2.—Relationship between saccharin and cyclamate concentration and neurite outgrowth in cultured DRG. To establish neurite outgrowth, DRG were incubated on rattail collagen-coated Microwell plates for 1 day with 2 ng NGF/ml (8×10^{-11} *M*) and the neurite length from the edge of the explant to the fiber tip was measured. Then various concentrations of artificial sweeteners were added, the incubations were continued for another day, and neurite length was measured again. The text-figure shows the *change* in neurite length between days 1 and 2: □, no additions; Δ, saccharin added; ○, cyclamate added.



TEXT-FIGURE 3.—Effect of saccharin and cyclamate concentration on [^{125}I]NGF binding to DRG cells. Cells from 9-day-old embryonic chick DRG were incubated for 1 hr with [^{125}I]NGF (2×10^{-10} *M*) and the indicated concentrations of sweeteners. Specific total (*open symbols*) and site I (*solid symbols*) bound radioactivity were assayed: □, no additions; Δ, saccharin added; ○, cyclamate added; ⬡, sucrose added; and ▽, glucose added. Values are means ± SE, *n*=3. *Inset* shows radioactivity bound to site II, defined as the difference between specific total and site I-bound radioactivity. Corresponding symbols are used.

Effect of Promoters on [^{125}I]NGF Affinity and Association Rate.

To study the mechanism by which binding to site I is inhibited, DRG cells were incubated with various concentrations of [^{125}I]NGF for 1 hour, a time sufficiently long to reach a steady state in binding, and enough saccharin or cyclamate was added to inhibit [^{125}I]NGF binding by more than 50% (text-fig. 4). The data, excluding binding to site II, were plotted according to Scatchard (*24*). There was no effect on the number of available high affinity sites, but the binding affinity (equilibrium constant of association) was reduced to about 20% and 25% of the control value by 50 m*M* saccharin and 80 m*M* cyclamate, respectively. Binding to a low affinity nonsaturable component was unaltered. Consistent with this finding, the binding isotherms shifted



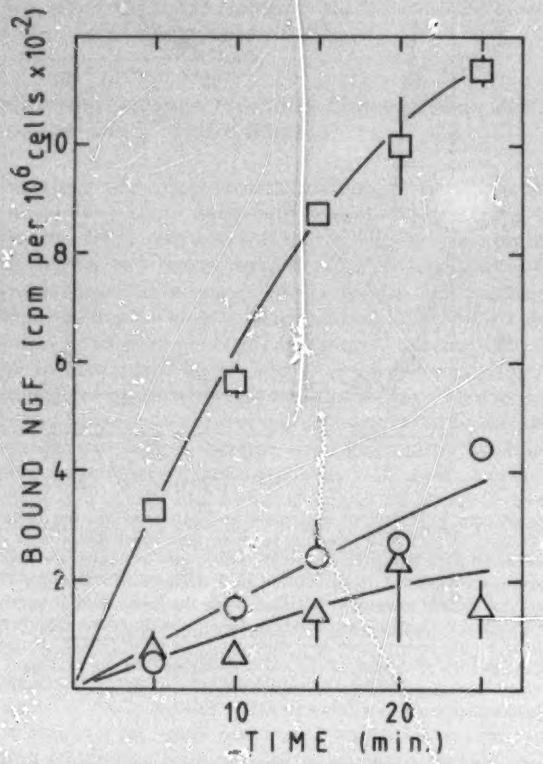
TEXT-FIGURE 4.—Effect of cyclamate and saccharin on the Scatchard analysis of [^{125}I]NGF binding to embryonic chick DRG cells. Cells obtained from 8-day-old embryonic DRG were incubated for 1 hr with various concentrations of [^{125}I]NGF alone (□) and with 50 m*M* saccharin (Δ), or 80 m*M* cyclamate (○). Binding to site I was assayed and values plotted according to Scatchard (*24*). *Inset* shows the relationship between bound radioactivity and low concentrations of [^{125}I]NGF. *Dashed line* indicates the saturation of site I as determined from the Scatchard plot. Units for bound NGF are in fmol/10^6 cells. The calculation of molarity is based on the dimer mol wt of 26,500 for NGF.

in parallel to the right when these agents were present (text fig. 4, inset).

The decreased affinity of [^{125}I]NGF binding could be due to a decrease in the association rate constant or to an increase in the dissociation rate constant. At the appropriately low concentration of 1.6×10^{-11} *M* [^{125}I]NGF, more than 95% of the radioactivity is estimated to bind exclusively to site I (*22*), permitting study of the association rate (text-fig. 5). Saccharin (50 m*M*) inhibited the initial velocity of binding to site I by 85% and 50 m*M* cyclamate by about 78%, inhibition values which could quantitatively account for the observed decrease in the affinity constant. Saccharin or cyclamate had no detectable effect on the rate of loss of bound radioactivity (data not shown). While these results suggest that inhibition is due to a decrease in the association rate, the data do not reveal whether the effect is direct or due to perturbation of other membrane components.

DISCUSSION

A number of tumor promoters are now known to be reversible inhibitors of morphologic differentiation in cells derived from the neural crest, and promoters can alter differentiation in many cell systems, possibly by a common mechanism of action.



TEXT-FIGURE 5.—Effect of saccharin or cyclamate on the initial rate of [^{125}I]NGF binding to site I on DRG cells. Cells from 9-day-old embryonic DRG were incubated with 0.40 ng [^{125}I]NGF/ml (1.6×10^{-11} *M*) alone (□), and with 50 m*M* saccharin (Δ), or 50 m*M* cyclamate (○). At various times aliquots were removed for assay of radioactivity bound to site I. Values are means ±SE, $n=3$.

The potent tumor-promoting macrocyclic plant diterpene esters inhibit neurite outgrowth in cultured DRG (*4*) and in mouse neuroblastoma cells (*5*), but structurally related nonpromoting congeners do not. The weak mouse skin promoter phenol (*25*) is an antagonist in DRG (*11*), whereas benzene and fluorobenzene are neither skin tumor promoters (*25*) nor inhibitors of neurite outgrowth (*11*). Moreover, I have found that deoxycholate, a promoter in colon (*26, 27*), also reversibly blocks neurite outgrowth (Ishii DN:Unpublished observation).

Promoters may act by altering the program of differentiation in a variety of cell types. Phorbol ester promoters inhibit fusion and myogenesis of cultured chick myoblasts (*28*), terminal differentiation of Friend erythroleukemia cells (*29, 30*), and conversion of 3T3 fibroblasts to adipose-like cells (*31*). These compounds can also induce phenotypic expressions associated with the normal differentiated state in myeloid leukemia (*32, 33*) and in melanoma (*34*) cells. Thus alteration of cellular differentiation, particularly because it was also reported in mouse skin (*35*), may be an important property of promoters.

While saccharin and cyclamate clearly inhibit NGF binding, TPA (*4, 36*) and phenol (*11*) do not, suggesting that tumor promoters may antagonize morphologic differentiation of neuronal cells by more than one mechanism. Interestingly, binding of epidermal growth factor to cultured mammalian cells is inhibited by the tumor-promoting phorbol esters (*36–38*). Binding of other ligands to the cell surface was not affected (*36*), suggesting specificity. This report shows that binding of other physiologically important polypeptides can be inhibited. The induction of globin mRNA in erythroleukemia cells is inhibited by TPA (*39*) during inhibition of terminal differentiation, indicating that promoters probably act prior to processing of transcripts and, possibly, prior to transcription itself. These data, together with my findings, support the tentative hypothesis that tumor-promoting compounds may alter the program of cellular differentiation in a variety of cell types by interacting with receptor systems regulating cellular functions. Various chemical classes of promoters may interact at different steps in a sequence of receptor-activated events; whether interaction results in induction or inhibition of differentiation will depend on the program of the involved receptor system in a particular tissue. This tentative hypothesis can be tested. It will be of interest to study the effect of TPA and other promoters on the early events following binding of NGF to its receptors.

Binding of [^{125}I]NGF has been studied by several groups (*21, 22, 40, 41*), but the biological significance of identified sites is not clearly established. These results strongly support the argument that site I is the putative NGF receptor for neurite outgrowth since saccharin or cyclamate cause a parallel dose-dependent inhibition of response and binding. These compounds will, hopefully, prove useful in further studies on NGF binding.

Granulopoiesis Longevity in Continuous Bone Marrow Cultures and Factor-Dependent Cell Line Generation: Significant Variation Among 28 Inbred Mouse Strains and Outbred Stocks [1, 2, 3]

Mary Ann Sakakeeny [4] *and* **Joel S. Greenberger** [4, 5, 6]

ABSTRACT—Longevity of granulopoiesis in corticosteroid-supplemented continuous bone marrow cultures and generation of permanent WEHI-3 dialyzed conditioned medium (DCM)-dependent hematopoietic progenitor cell lines were evaluated for 28 inbred mouse strains and outbred stocks. Cultures from AKR/J, NZW, C58/J, DBA/2J, and C57BL/KsJ mice generated granulocytes for 45–58 weeks and released more than 10^5 murine sarcoma virus (MuSV) rescue units of endogenous retrovirus; nonadherent (NA) cells from 50% or more cultures produced permanent WEHI-3 DCM-dependent cell lines. Cultures from 129/J, BALB/cJ, SJL/J, RF/J, CD-1 Swiss, C57BR/cdJ, C57BL/Ka, CBA/J, RFM/Sn, NZB, C3H/HeJ, NIH Swiss [N:NIH(S)], C57BL/10J, C57L/J, SWR/J, HRS/J, and C57BL/6J mice generated granulocytes for 12–38 weeks; some released 10^1–10^2 MuSV rescue units of retrovirus, and NA cells from less than 50% of cultures from all but SWR/J and C57L/J mice produced WEHI-3 DCM-dependent cell lines. Thus longevity of granulopoiesis in mouse continuous bone marrow cultures varies significantly among strains.—JNCI 1982; 68: 305–317.

The development of a method for maintenance and proliferation of pluripotential hematopoietic stem cells in vitro from a single bone marrow inoculum (*1–3*) has led to a number of studies of the biology of normal and abnormal hematopoiesis in vitro (*3–15*). The initial difficulty with reproduction of the system of Dexter and Testa (*1*) has been overcome by addition of 17-hydroxycorticosteroid at a concentration of 10^{-7} to 10^{-5} *M* to horse serum or FCS and sustains hematopoiesis in vitro for several months (*2*). The addition of hydrocortisone to long-term bone marrow cultures also eliminates the need for addition of a second marrow inoculum at 3–4 weeks (recharge) as initially described by Dexter and Testa (*1*). While longevity of hematopoiesis in murine continuous bone marrow cultures is improved by corticosteroid, differences in culture longevity between laboratories (*1, 2, 7, 13, 16–18*) suggested that mouse strain genotype might independently influence the duration of hematopoiesis in vitro. Furthermore, cells removed from continuous bone marrow cultures of some (*6, 14*), but not all (*6, 9*), mouse strains form permanent lines of self-renewing hematopoietic progenitor cells if transferred to suspension culture in DCM from the WEHI-3 cell line (*9, 19*) or pokeweed mitogen spleen cell-conditioned medium (*8*). The observation that infection of cultures from N:NIH(S) mice with specific murine leukemia viruses prolonged the duration of granulopoiesis in primary cultures and induced formation of WEHI-3-dependent cell lines (*9, 10*) indicated that regulation of self-renewal of hematopoietic cells in vitro was altered by retrovirus replication. The site(s) and mechanism of action of retrovirus replication on hematopoietic and/or adherent stromal cells in the cultures are unknown.

In the present studies, we evaluated the role of genetic variables, including endogenous retrovirus replication, in regulation of hematopoiesis in long-term bone marrow cultures from 20 inbred mouse strains, four F_1 hybrid strains, and several F_2, backcross, and outbred mouse stocks. We specifically sought to determine *a*) whether longevity of hematopoiesis was associated with spontaneous induction of replication of endogenous ecotropic retrovirus, as suggested by previous studies (*7*); *b*) whether stromal and/or hematopoietic stem cell genotype regulated longevity; and *c*) whether longevity could be correlated with differences in the morphology of NA cells, including maintenance of adipocytes in the adherent cell layer.

MATERIALS AND METHODS

Mice.—Mice were obtained from The Jackson Laboratory, Bar Harbor, Maine, and included the following: AKR/J, BALB/cJ, CBA/J, C57BL/6J, C57BL/10J, C57BL/KsJ, C57BR/cdJ, C3H/HeJ, C58/J, C57L/J, DBA/2J, RF/J, SJL/J, SWR/J, 129/J, HRS/J,

---

ABBREVIATIONS USED: CFU$_c$=colony-forming unit(s) of progenitor cells; CSF=colony-stimulating factor(s); DCM=dialyzed conditioned medium; FCS=fetal calf serum; GM=granulocyte-macrophage; GM-CFU$_c$=CFU$_c$ of GM progenitor cells; MuSV=murine sarcoma virus; K-MuSV=Kirsten MuSV; NA=nonadherent.

(C57BL/6J × DBA/2)F_1 [(B6D2)F_1/J] and (C3H/HeJ × DBA/2J)F_1 [(C3D2)F_1/J]. C57BL/Ka mice were provided by Dr. Alain DeCleve and Dr. Henry Kaplan, Stanford University, Palo Alto, Calif. CD-1 Swiss mice were obtained from the Charles River Breeding Laboratories, Boston, Mass. NIH Swiss [N:NIH(S)], NZB, and NZW mice were obtained from the Small Animal Section, Veterinary Resources Branch, Division of Research Services, National Institutes of Health, Bethesda, Md. RFM/Sn mice were provided by Dr. Harvey Preissler, Roswell Park Memorial Institute, Buffalo, N.Y. (CBA/J × C57BL/6J)F_1, [N:NIH(S) × C57BL/KsJ]F_1, [NIH:NIH(S) × C57BL/KsJ]F_1 × N:NIH(S) backcross, and [(N:NIH(S) × C57BL/KsJ]F_2 mice were bred in our laboratory. All mice were standardized to 30–33 g, and only female mice were used unless otherwise designated.

Cell lines.—Cells were grown in Dulbecco's modified Eagle's minimum essential medium with 10% FCS and included embryo fibroblast lines NIH/3T3 (*20*) and BALB/3T3 (*21*) and a normal rat kidney line, NRK (*22*). A K-MuSV-transformed nonproducer cell line of each has been described; they are termed KNIH, KBALB, and KNRK, respectively (*23*).

The cell lines L929 and WEHI-3 clone 5 (*15*) have been reported. Conditioned medium was harvested from each line after growth at 37°C for 72 hours. For WEHI-3 conditioned medium was then dialyzed against a hundredfold excess of distilled water for 72 hours. The dialysate was then concentrated fivefold by Amicon PM10 filtration (Amicon Corp., Lexington, Mass.) according to published procedures. The resulting DCM was added in a 10% volume to McCoy's 5-A supplemented medium (*11*) with 15% FCS (Flow Laboratories, Inc., Rockville, Md.).

Virus assays.—A method for detection of retrovirus virion-associated reverse transcriptase in the culture fluid of normal long-term bone marrow cultures has been reported previously (*9*). A focus assay has been described for detection of low levels of infectious retrovirus by 7 days' cocultivation of marrow culture cells with exponential phase cultures of KNIH, KBALB, or KNRK cells followed by transfer of this culture medium in serial tenfold dilutions to exponential phase cultures of Balb/3T3, NIH/3T3, and NRK cells for focus assay of rescued K-MuSV (*7*). Virus detected by rescue of K-MuSV from KNIH cells with focus formation on NIH/3T3 cells was designated N-tropic according to published criteria of host range for infectivity (*24*). The level of virus production was designated as the end-point dilution at which K-MuSV was rescued (MuSV rescue units) (*7*).

Long-term bone marrow cultures.—The contents of a tibia and femur were flushed via a 22-gauge needle into Corning plastic flasks (40 cm^2) in 10.0 ml Fisher's medium supplemented with 10^{-5} *M* hydrocortisone sodium hemisuccinate (Solu-Cortef; The Upjohn Co., Kalamazoo, Mich.) and 25% horse serum (Flow Laboratories, Inc., Rockville, Md.). Cultures were maintained at 33°C in a high-humidity incubator (Wedco, Rockville, Md.) with 7% CO_2 and were fed by weekly removal of all NA cells and medium with replacement by a 10.0-ml volume of fresh medium. Cultures were not recharged with any additional marrow. By week 4, all cultures were switched to weekly refeeding with 8.0 ml of medium containing 25% FCS with 10^{-5} *M* hydrocortisone (*3*).

Hematopoietic colony-forming cell assays.—The assay for GM-CFU$_c$ (*25*) has been described. The method for quantitation of adipocyte colonies (≥50 cells) and clusters (10–49 cells) in primary marrow cultures was reported previously (*2, 3*).

Establishment of permanent WEHI-3 DCM-dependent hematopoietic progenitor cell lines.—NA cells from individual marrow cultures were centrifuged to a pellet (1,000×*g* for 10 min) and transferred at 5×10^5 cells to 4.0-ml petri dishes containing McCoy's 5-A supplemented medium (*9, 10*) and 10% WEHI-3 DCM (*11*). The methods for establishing cloned cell lines and for preparing dialyzed, Amicon filtration-concentrated WEHI-3 conditioned medium have been reported previously (*11*).

Histochemical and hematologic staining.—The methods for detection of intracellular myeloperoxidase, lysozyme, esterase-M (ASD-chloroacetate substrate-specific), and metachromasia by toluidine blue dye (*26–30*) have been described. Metachromasia has been shown to be a reliable indicator of mast cell–basophil differentiation of GM-CFU$_c$, derived from long-term marrow cultures and correlates with intracellular synthesis of histamine and the presence of surface IgE receptors (*28*). The Wright's–Giemsa staining technique was used as reported previously (*30*).

Assay for in vivo leukemogenicity.—Cell lines grown in WEHI-3 DCM were inoculated ip into newborn mice on the 1st day of life or iv into adult 30- to 33-g mice of each indicated strain. Mice were observed weekly for lymph node or spleen enlargement and peripheral blood leukocyte counts. According to published methods (*9*), dead or dying mice were subjected to complete postmortem evaluation of liver, spleen, lymph nodes, bone marrow, and central nervous system.

RESULTS

Continuous bone marrow cultures were established from the contents of a femur and tibia of each of the mouse strains shown in table 1. Each experiment for each strain contained at least eight cultures (femurs and tibias from four mice); cultures were initiated in 25% horse serum supplemented with 10^{-5} *M* hydrocortisone and switched by day 28 (the fourth weekly feeding) to 25% FCS with the same hydrocortisone concentration. At least two separate experiments containing at least eight flasks each were performed with each mouse strain or stock. To minimize variation due to differences in lots of horse serum or FCS, we reserved specific lots of serum for use exclusively in these experiments. Cultures were maintained at 33°C, and assays for GM-CFU$_c$ were performed with the use of a single preparation of L929 cell-conditioned medium as a source of CSF. Cultures were incubated at 37°C and scored by one observer (M. A. S.) on day 7. Thus differences in the biologic properties between the strains could not be attributed to differences in culture conditions.

Each culture had the medium changed every 7th day, according to published procedures (*3*), by removal of all NA cells and medium and replacement by a fresh volume of medium. Cells from each group of cultures were spun to a pellet at 1,000×g for 10 minutes, resuspended in 4.0 ml of McCoy's 5-A medium supplemented with 10% WEHI-3 DEM, and maintained at 31°C with passage every 3d day as described in "Materials and Methods." The number of cultures generating a suspension cell line from 5×10^5 NA cells, which could be maintained continually with passage twice a week and could be cloned in 0.3% agar, was determined for each strain in each experiment. Extra NA cells from all the cultures of each strain were then pooled and prepared for differential cell count and GM-CFU$_c$ assay.

Longevity of Granulopoiesis and Generation of WEHI-3 DCM-Dependent Cell Lines: Significant Variation Among Mouse Strains

As shown in table 1, the duration of generation of mature granulocytes and cells that formed GM-CFU$_c$ (>50 cell colonies in 0.3% agar supplemented with L929 cell CSF) varied significantly among strains. Cultures from AKR/J, NZW, DBA/2J, and C58/J marrow produced granulocytes for over 50 weeks and generated GM-CFU$_c$ for at least 40 weeks. Within each of these strains, individual cultures varied, but the range of fluctuation was less than 20% of the mean (table 1). NA cells from at least 50% of cultures from each of these strains generated permanent cell lines in WEHI-3 DCM. Marrow cultures from C57BL/KsJ mice generated granulocytes and GM-CFU$_c$ for at least 40 weeks, and a very high fraction of cultures (10/16) generated WEHI-3 DCM-dependent cell lines. The earliest culture harvest generating a permanent line was detected at week 4 with AKR/J and NZW marrow, but the cultures produced NA cells that were capable of forming cell lines for very long periods (with AKR/J up to 40 wk). Continuous bone marrow cultures established from 129/J, BALB/cJ, SJL/J, RF/J, CD-1 Swiss, C57BR/cdJ, C57BL/Ka, CBA/J, RFM/Sn, NZB, C3H/HeJ, and N:NIH(S) mice generated mature granulocytes and GM-CFU$_c$ for periods ranging between 25 and 38 weeks. In each case, the decline of hematopoiesis was associated with a relative increase in the percentage of macrophages detected in NA cell harvests and decreased numbers of hematopoietic cell islands in the adherent compartment of the culture. These adherent islands have previously been shown by use of the inverted microscope to consist of flat cells with rounded, rather than polygonal or elongate, shape and a nonrefractile appearance (*15*). The morphologic appearance of such tightly interlocking round cells has been termed "cobblestone areas." Round, refractile hematopoietic cells were observed to evolve in sheets from these cobblestone areas, and cessation of hematopoiesis was associated with decreased numbers of such cobblestone areas (*15*).

The density of cobblestone areas in cultures at weeks 4 and 8 was compared for AKR/J, NZW, C57BL/KsJ, 129/J, N:NIH(S), and C3H/HeJ mice. The morphology of cultures at weeks 4 and 8 was indistinguishable among representatives of each group when scored for the percentage

[a] Groups of at least 16 cultures were established from the contents of femur and tibia marrow from mice of each indicated strain or stock. All cultures were initiated in 25% horse serum and switched at day 28 (the fourth weekly feeding) to 25% FCS. Fresh hydrocortisone (10^{-6} *M*) was added weekly. F_1 and F_2 hybrid mice and backcross mice were bred or obtained as described in "Materials and Methods."

[b] Total removed cells were counted, and the mean cell No. produced per week per culture was recorded. Results are presented as the mean longest duration of production of at least 10^4 granulocytes/wk for each culture. The range of production of 10^4 cells/culture is also shown for each group.

[c] Results represent the mean and range of duration of production of at least one ≥50-cell GM-CFU$_c$ colony/5×10^4 cells in 10% L929-conditioned medium as a source of CSF. The mean and range of GM cluster production (10–49 cells/colony) are not shown but averaged 1–2 wk longer than those for GM-CFU$_c$.

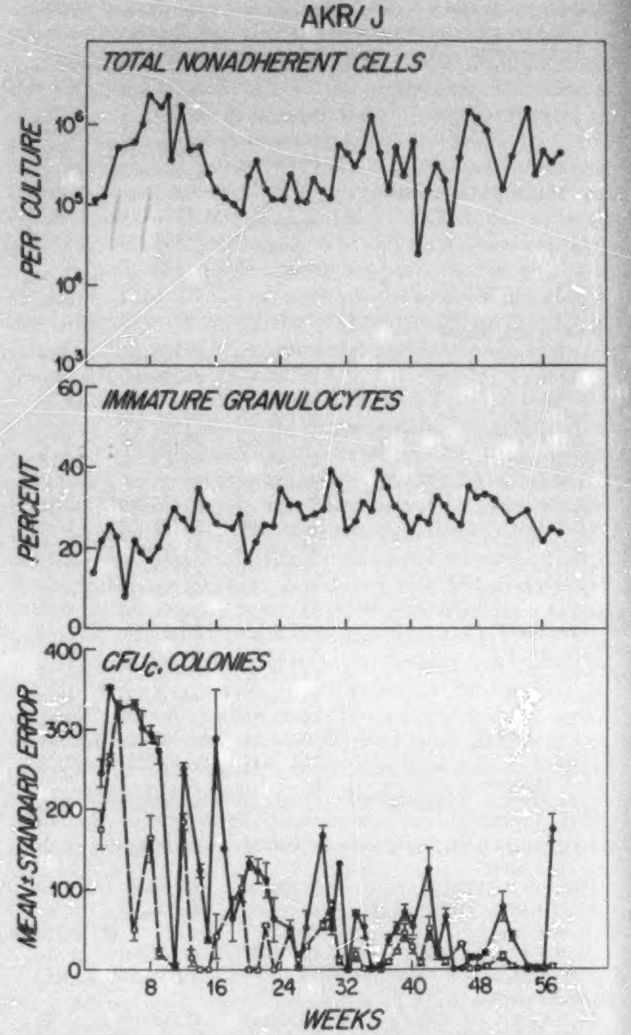
[d] The NA cells from each group of cultures after cells were removed for GM-CFU$_c$ assay and hematologic staining were centrifuged to a pellet and transferred to suspension cultures in McCoy's 5-A supplemented medium containing 10% concentrated (five times) WEHI-3 DCM (11). The No. of cultures in each group establishing a permanent cell line that sustained exponential phase growth in suspension culture for >10 mo is shown over the total No. of cultures tested.

of surface area covered by cobblestone areas and percentage of culture surface area covered by adherent fibroblast-like cells or adipocytes. Thus the appearance of long-term marrow cultures at early time points (before wk 8) did not predict the ultimate longevity of the cultures.

Continuous marrow cultures from C57BL/10J, C57L/J, SWR/J, C57BL/6J, and HRS/J mice showed longevity ranging from 12 to 24 weeks. The decreased longevity of cultures from HRS/J mice compared to that of AKR/J mice was highly significant (P<0.001) as was the difference between cultures from either AKR/J or C57BL/Ks/J and C3H/HeJ or C57BL/6J mice (P<0.02). There were no visible differences as judged by inverted microscopic examination of culture groups, except that HRS/J cultures began to demonstrate decreased cobblestone islands and decreased density of NA cells at week 6.

Generation of GM-CFU$_c$ by cultures from each of the inbred strains fluctuated from week to week. This phenomenon could not be correlated with differences in the total number of cells produced during a particular week or to the percentage of immature cells detected that week. As shown in text-figure 1, AKR/J long-term marrow cultures generated GM-CFU$_c$ for over 56 weeks. The peaks of production of GM-CFU$_c$ seen at weeks 31, 42, and 50, when cells were plated at 2×10^5/dish, were not associated with increases in the percentage of immature granulocytes at those time points. Immature granulocytes ranged between 20 and 30% of cells in the culture. The peaks of GM-CFU$_c$ also did not correlate with increases in the total number of NA cells removed at that time point. Total cell numbers varied between 10^5 and 5×10^6 cells/culture.

Fluctuation in production of GM-CFU$_c$ also occurred in marrow cultures from NZW, DBA/2J, and C58/J marrow cultures (text-figs. 2-4), although in NZW cultures an increased number of GM-CFU$_c$ was detected between week 36 and week 44 compared to that for weeks 4-12. An increased relative number of GM-CFU$_c$ was also seen between week 30 and week 44 compared to that for earlier weeks in DBA/2J and C58/J marrow cultures. A similar fluctuation in production of GM-CFU$_c$ was seen in marrow cultures from strains with decreased in vitro longevity. As shown in text-figure 5, cultures from 129/J mice produced GM-CFU$_c$ that cycled rapidly between week 1 and week 24, with the greater numbers of colonies detected at the higher plating density (2×10^5) compared to those at the lower (5×10^4) one. A fluctuation was also seen in cultures from SJL/J, C57BR/cdJ, and C57BL/10J mice (text-fig. 6; data not shown). The percentage of immature granulocytes scored in cultures from 129/J and SJL/J mice was significantly lower than that in cultures from AKR/J, NZW, DBA/2J, or C58/J mice. Cultures from those strains with decreased longevity were also observed to have a persistently lower percentage of immature granulocytes in the removed cell number; however, there was no detectable difference in the absolute number of cells removed among strains with long and short durations of hematopoiesis. Cultures from C57BR/cdJ, C57BL/10J, RF/J, NZB, C57L/J, CBA/J, C57BL/6J, and SWR/J mice persistently demonstrated less than 25% immature granulocytes in the harvests between week 1 and week 20 (text-fig. 7; data not shown). Included in the designation of immature granulocytes are cells with blast, promyelocyte, or myelocyte morphology. Excluded are cells with toluidine blue-positive mast cell–basophil granules, megakaryocytes, and multinucleated cells including detached macrophages.



TEXT-FIGURE 1.—Granulopoiesis in continuous marrow cultures from AKR/J mice. Results represent the mean total NA cells counted per culture each week in the total volume of medium removed that week. Loosely adherent cells were not washed off. At least six cultures in each of 2 expts were counted at each time point. The percent immature granulocytes is based on a differential cell count of a Wright's–Giemsa-stained preparation of NA cells removed each week and is the mean of at least three counts at each point scoring 1,000 cells/slide. The No. includes blasts, promyelocytes, and myelocytes excluding detached macrophages, megakaryocytes, and subtraction of the percent mast cell–basophils scored on parallel toluidine blue-stained slides. The standard error was <10% of the mean for these determinations. The CFU$_c$ are the mean ± standard error of the mean for GM colonies of ≥50 cells/colony scored at day 7 following incubation at 37°C of 2×10^5 (●) or 5×10^4 (○) NA cells/1.0 ml culture containing 0.3% agar. (Text-figs. 2–8 are prepared in an identical fashion.)

The number of NA cells recovered weekly from cultures of each strain clearly fluctuated. This fluctuation was often precipitous, as seen in the variation of cells removed weekly from NZB cultures (text-fig. 8). In contrast, AKR/J cultures produced a consistently higher number of cells that fluctuated over a shorter tenfold range (10^5–10^6) per week, compared to the fluctuations in NZB cultures over a hundredfold range (10^4–10^6). An overall trend toward decreased production of cells per week was observed with each strain tested; however, the plateau of production lasted over 56 weeks for AKR/J cultures (text-fig. 1), over 52 weeks for NZW cultures (text-fig. 2), and for a much shorter duration with strains such as NZB (text-fig. 8). In cultures that produced GM-CFU$_c$ and/or granulocytes at more than 10^4/culture/week for over 40 weeks, a gradual decline in the total cell number produced per week correlated with an increase in the relative percentage of macrophage-like cells in the NA cell harvest. The decrease in cell number is shown for C58/J cultures in text-figure 4 and for 129/J cultures in text-figure 5 and is compared to that for the shorter duration cultures of NZB marrow in text-figure 8 and of SWR/J marrow in text-figure 7. In DBA/2J cultures, a downward trend in cell numbers was observed from weeks 8 to 32 followed by a gradual increase in the production of GM-CFU$_c$ and total cell numbers between week 36 and week 48. A second increase in cell number was associated with a gradual increase in the percentage of immature granulocytes also seen at that time (text-fig. 3). In each of the strains tested, the number of GM-CFU$_c$ was greater at the high cell density (2×10^5/ml) compared to that at the lower cell density (5×10^4/ml) (text-figs. 1–8), arguing against production of NA inhibitory cells for the GM-CFU$_c$.

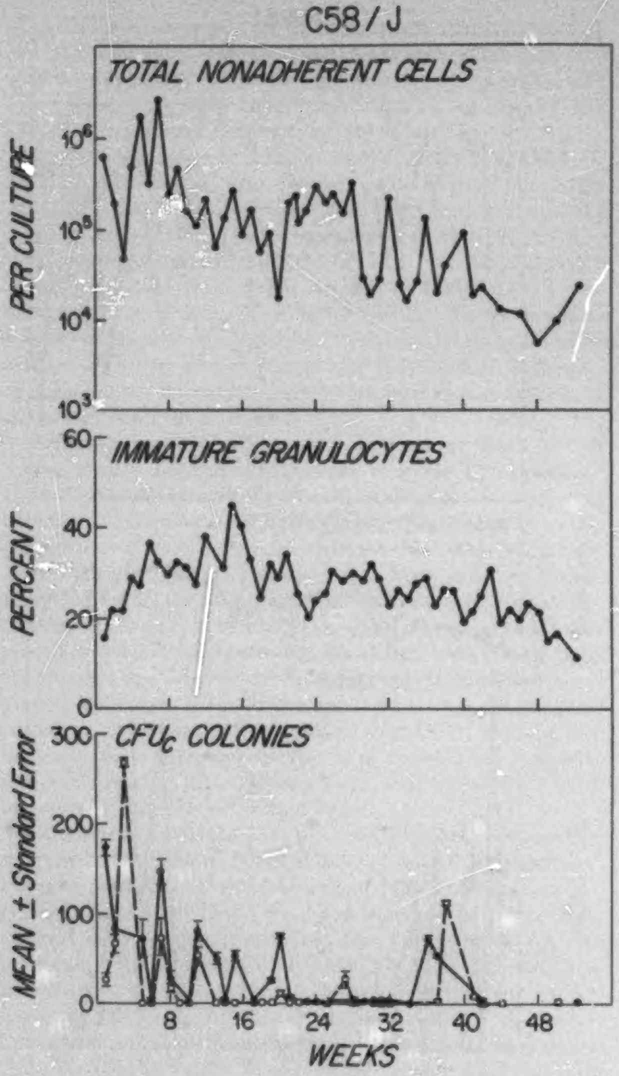
TEXT-FIGURE 3.—Granulopoiesis in continuous marrow cultures from DBA/2J mice.

The morphology of GM-CFU$_c$ produced in cultures from representative strains at extremes of the spectrum was tested next. GM-CFU$_c$ produced at week 50 by C57BL/KsJ and

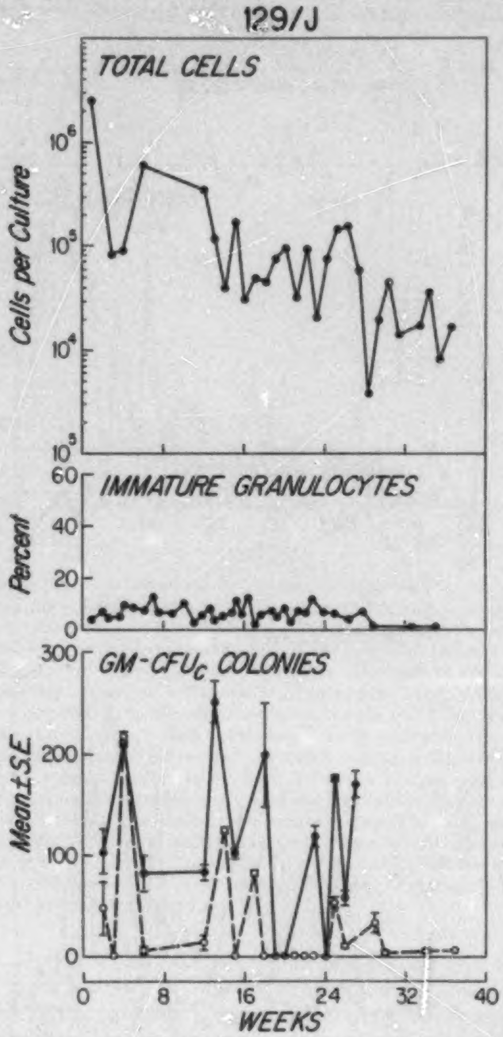


Text-figure 4.—Granulopoiesis in continuous marrow cultures from C58/J mice.

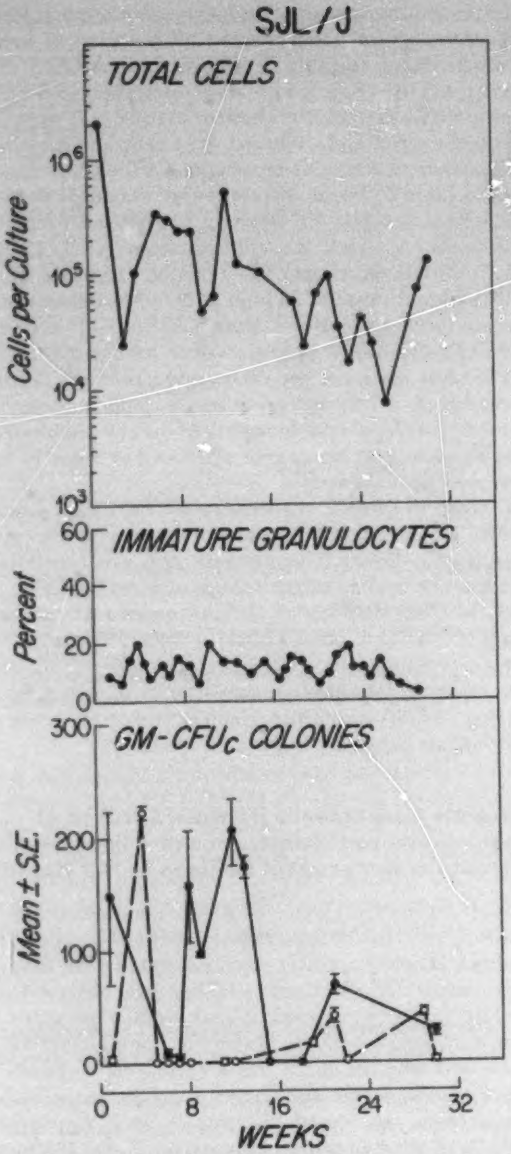
AKR/J were 82–85% macrophage and 15–18% mixed GM (range for 6 separate expts). GM-CFU$_c$ produced by these same cultures at earlier time points were not detectably different and did not differ from GM-CFU$_c$ produced at week 10 by HRS/J cultures (83–86% macrophage and 16–17% GM).

Duration of Hematopoiesis Influenced by a Mendelian Genetic Mechanism

Several F$_1$ hybrid strains were next tested to determine whether longevity of hematopoiesis in long-term marrow cultures was a dominant or recessive trait or whether it was regulated by a more complex genetic mechanism. Results with several of these hybrids are shown in table 1. For these studies at least four separate experiments with eight cultures per strain were performed. (B6D2)F$_1$ marrow cultures derived from a DBA/2 parent, with a mean longevity of 48 weeks, and a C57BL/6J parent, with a duration of hematopoiesis of 20 weeks, demonstrated longevity similar to that of the DBA/2 parent with generation of granulocytes for 51 weeks and GM-CFU$_c$ for 50 weeks. Similarly, (C3D2)F$_1$ mice demonstrated characteristics similar to those of the DBA/2 parent with generation of granulocytes for 41 weeks and GM-CFU$_c$ for 40 weeks. The F$_1$ hybrid between CBA/J and C57BL6/J mice demonstrated an intermediate longevity of 23 weeks for production of granulocytes and of 23 weeks for production of GM-CFU$_c$. Data with three F$_1$ strains indicated that longevity was dominant if measured by mean duration of hematopoiesis. The range of individual cultures within each F$_1$ group indicated that the longevity of most cultures in the group was increased above that of the short-duration parent strain. NA cells from each F$_1$



Text-figure 5.—Granulopoiesis in continuous marrow cultures from 129/J mice.



TEXT-FIGURE 6.—Granulopoiesis in continuous marrow cultures from SJL/J mice.

hybrid tested generated permanent WEHI-3 DCM-dependent cell lines (table 1).

Examination of cultures from [N:NIH(S) × C57BL/-KsJ]F$_1$ mice was next done and revealed an intermediate longevity, which was, however, closer to that of the long-duration parent C57BL/KsJ. These F$_1$ cultures generated GM-CFU$_c$ for 40 weeks and granulocytes for 43 weeks. To determine if longevity segregated in genetic crosses, we derived F$_2$ hybrid mice from N:NIH(S) and C57BL/KsJ mice and backcross mice of the F$_1$ generation on the shorter duration N:NIH(S) parent. Results with these cultures are shown in table 1 and indicate that longevity was consistently higher than that for the short-duration parent; however, the range of individual cultures widened as the genetic influence of the N:NIH(S) parent was increased in backcross and F$_2$ strains.

Two outbred stocks of Swiss mice were next compared: CD-1 Swiss and N:NIH(S). As shown in table 1, the longevity of hematopoiesis between the two stocks was not significantly different; however, generation of WEHI-3 cell-conditioned medium-dependent lines was markedly different. Combined results from experiments done over 3 years with N:NIH(S) mice are included for reference. No permanent lines were obtained from NA cells removed from N:NIH(S) cultures; however, 4 of 16 cultures from CD-1 Swiss marrow generated permanent cell lines.

Concordance Between Magnitude of Production of Immature Granulocytes and Duration of Production of GM-CFU$_c$ in Marrow Cultures of Different Mouse Strains

Table 2 shows the mean numbers of NA cells produced at weeks 10, 20, 30, and 40 for groups of cultures from each of 17 representative mouse strains and stocks. The magnitude of cell production at week 10 did not reflect the subsequent longevity of hematopoiesis. For example, RF/J long-term marrow cultures produced 3×10^6 cells/culture at week 10 and continued to produce granulocytes or GM-CFU$_c$ for 24 weeks. In contrast, NZW cultures produced fewer cells (5.0×10^5) per culture at week 10 but maintained hematopoiesis for 51 weeks. Thus the magnitude of cell production at the early time point did not reflect the overall longevity of the cultures. These experiments also confirmed our observation that density of cobblestone and round cell areas in the cultures at the early time of 10 weeks could not predict long-duration cultures.

The percent immature granulocytes generated at week 10 more accurately reflected the overall duration of hematopoiesis. As shown in table 2, cultures from AKR/J, NZW, DBA/2J, C57BL/KsJ, and C58/J mice produced 16–38% immature cells at week 10. These immature cells were of the granulocyte series and excluded mast cells and multinucleated megakaryocytes or macrophages. Of the 12 other strains shown in table 2, 5 demonstrated more than 16% immature granulocytes at week 10, whereas 7 produced consistently lower levels. At week 20, cultures from AKR/J, NZW, DBA/J, C57BL/KsJ, and C58/J mice produced at least 15% NA immature cells; as high as 36% NA immature cells were produced by cultures from C57BL/KsJ. Of the 12 other strains shown, 3 produced over 15% immature cells. Thus in most instances the early production and increased percentage of immature granulocytes appeared to more accurately predict overall longevity of the cultures compared to the absolute number of cells produced at week 10 for 17 strains and stocks tested.

As shown in table 2, the density of GM-CFU$_c$ produced at week 10, 20, or 30 did not correlate with the overall longevity of cultures. This phenomenon was attributed to fluctuation or cycling of the release of NA GM-CFU$_c$ (text figs. 1–8). Thus analysis of differences between strains by looking at one time point either at week 10 or at week 20 did not accurately predict the overall longevity of the cultures; however, persistent production of a relatively high percentage of NA immature granulocytes (>10%) best predicted culture longevity beyond 30 weeks.

Incomplete Concordance Between Duration of Hematopoiesis and Maintenance of Adipocytes in Adherent Compartment of Cultures or *H-2* Haplotype

Initial studies by Dexter et al. (*31*) indicated that fat-containing cells in the adherent microenvironment of long-term bone marrow cultures were associated with long-term hematopoiesis. To determine whether cells observed to accumulate fat between week 1 and week 4 persisted over longer duration in cultures producing granulocytes for long periods and whether there was a correlation between persistence of adipocytes and longevity of hematopoiesis between strains, we scored cultures of each mouse strain weekly, according to published criteria (*2*), for the number of adipocyte colonies and clusters seen in the adherent microenvironment. As shown in table 3, there was no concordance between the duration of granulopoiesis as reflected in the production of GM-CFU$_c$ and the duration of detectable adipocytes in the adherent layer of the cultures. Adipocytes were seen for 17 weeks in AKR/J cultures that generated GM-CFU$_c$ for 56 weeks. In contrast, adipocytes were seen for 37 weeks in cultures from N:NIH(S) mice, while hematopoiesis persisted for 21 weeks. Adipocytes were detected for 21 weeks in cultures from SWR/J, DBA/2J, C58/J, and CD-1 Swiss mice. The difference in longevity of hematopoiesis between SWR/J (18 wk) and DBA/2J (48 wk) was significant ($P<0.001$), whereas adipocyte maintenance was not detectably different ($P>0.5$).

There was no detectable correlation between a specific *H-2* haplotype and duration of hematopoiesis. C57BL/KsJ

[a] NT=not tested.

[b] Results for 17 representative strains and stocks are presented in decreasing order of longevity as measured in duration of production of detectable L929 CSF-responsive GM-CFU$_c$.

[c] Results are the means of at least eight cultures counted at that week.

[d] Results are presented as the mean percents of NA cells classified as blasts, promyelocytes, or myelocytes. Excluded are mast cells, macrophages, and megakaryocytes.

[e] Results are presented as the means of four GM-CFU$_c$ cultures scored at each cell plating density (2×10^5/5×10^4 NA cells/culture) and are for ≥50 cell colonies scored at day 7 after incubation at 37°C in 7% CO_2 and 0.3% agar containing 10% L929-conditioned medium and 15% FCS.

marrow cultures (*H-2^d*) produced granulocytes for 45 weeks, and cultures from DBA/2J (*H-2^d*) marrow produced granulocytes for 48 weeks. However, cultures from BALB/cJ (*H2^d*) marrow produced granulocytes for 33 weeks, a significantly shorter time (P<0.02). Both AKR/J and CBA/J mice have the *H-2^k* haplotype, and hematopoiesis varied significantly from 56 weeks with AKR/J to 19 weeks with CBA/J (P<0.02).

Concordance of Longevity of Granulopoiesis with High-Level Replication of Endogenous Retrovirus

Detectable spontaneous induction of endogenous retrovirus replication was next correlated with the longevity of hematopoiesis. As shown in table 4, AKR/J, NZW, DBA/2J, C57BL/KsJ, and C58/J long-term marrow cultures generated granulocytes for over 40 weeks and spontaneously released N-tropic endogenous virus. The level of virus released was more than 10^5 MuSV rescue units for each of these strains (table 4). In contrast, CBA/J, C57BL/6J, and BALB/cJ marrow cultures also released N-tropic virus but at a significantly lower level (10^1-10^2 MuSV rescue units) and generated granulocytes for 19 weeks (33 wk for BALB/cJ). While 129/J long-term marrow cultures produced granulocytes for 38 weeks, these cultures did not release detectable N-tropic virus. Thus spontaneous induction of detectable endogenous virus replication did not absolutely correlate with longevity of hematopoiesis. There was a positive correlation between high-level replication of retrovirus and longevity of hematopoiesis beyond 40 weeks (P<0.05).

Lack of Concordance Between Duration of Production of Basophil–Mast Cells or Lymphocytes and Neutrophilic Granulocytes

To determine whether production of a morphologically detectable NA helper cell or inhibitory cell accounted for variations in duration of hematopoiesis, we tested weekly NA cells from five representative strains for production of morphologically recognizable megakaryocytes, erythroid cells, lymphocytes, monocytes, plasma cells, or toluidine blue-positive mast cell–basophils. As shown in table 5, there was no correlation between longevity of production of granulocytes and the number of weeks during which basophil-mast cells were detected in the NA cell compartment. C57BL/KsJ marrow cultures produced detectable mast cells for 7 weeks and mature granulocytes for 45 weeks. In contrast, while N:NIH(S) cultures also produced basophil-mast cells for 7 weeks, granulocytes were generated for 25 weeks, a significantly shorter duration (P<0.01). No correlation was observed if duration of granulopoiesis was compared to numbers of NA megakaryocytes, monocytoid or lymphoid cells, or plasma cells detected in the NA compartment (data not shown).

Effect of Genotype of Adherent Stromal Cells and NA Hematopoietic Stem Cells on Longevity of Hematopoiesis in Mixed Marrow Cultures

To determine whether the longevity of AKR/J and C57BL/KsJ marrow cultures was a property of the adherent and/or NA cell population, we established, according to published methods (15), purified stromal cell cultures from

[a] NA cells harvested weekly were assayed, according to published procedures (*28*), for the No. of metachromasia-positive cell lines by toluidine blue staining. Results are presented as the mean No. of weeks during which at least one mast cell–basophil was detected/10^4 NA cells harvested compared to the mean duration of production of neutrophils/culture.

each strain by corticosteroid deprivation. NA cells from other corticosteroid-rich cultures were harvested at week 8 and engrafted to each syngeneic or allogeneic population at 5×10^6 NA cells/culture (*15*).

As shown in table 6, AKR/J or C57BL/KsJ NA cells proliferated in vitro for a significantly longer period on syngeneic or allogenic stromal cell cultures, including those from strains with a shorter duration of hematopoiesis following addition of their own syngeneic hematopoietic cells. For example, AKR/J NA cells engrafted to C3H/HeJ stromal cultures produced granulocytes for more than 20 weeks, whereas C3H/HeJ stromal cultures receiving syngeneic C3H/HeJ NA cells produced granulocytes for 8 weeks ($P<0.001$). In the reciprocal mix C3H/HeJ NA cells engrafted to AKR/J cultures produced granulocytes for 6 weeks, a shorter duration ($P<0.01$). The data indicate that the longevity of AKR/J marrow cultures compared to that of C3H/HeJ cultures was attributable to cells in the AKR/J NA cell compartment. When transferred to empty plastic flasks, AKR/J 8-week NA cells produced granulocytes for 2 weeks. These results confirm previous studies showing that stromal adherent cells are required for in vitro proliferation of 8-week NA cells harvested from murine continuous marrow cultures (*15*).

DISCUSSION

The present studies with 28 inbred mouse strains and outbred mouse stocks demonstrate significant differences in

TABLE 6.—*Effect of source of purified hematopoietic stem cells or stromal cells on longevity of reconstituted mouse bone marrow cultures*

Source of purified stromal culture[a]	Source of purified hematopoietic stem cells[b]					
	Long duration, wk		Intermediate duration, wk

CD-1 Swiss	>20	NT	NT	NT	NT	NT

[a] Groups of 20 marrow cultures were established as described in "Materials and Methods"; however, with the use of 25% FCS and no added corticosteroid as in (*15*), cultures were medium changed as described in "Materials and Methods," and at day 28 representative cultures were scraped to remove NA cells and adherent cells and tested for GM-CFU$_c$ formation. Under these conditions, <1 GM-CFU$_c$/10^5 cells was detected. These groups were then used as recipient purified stromal cultures.

[b] Longest duration generation of 10^4 granulocytes/culture/wk. NA cells from corticosteroid-rich cultures of each strain were removed at wk 8 and transferred at 5×10^6 cells to each culture of purified stroma. Reconstituted cultures were then weekly medium changed, and NA cells were tested for granulocyte morphology and GM-CFU$_c$ as described in "Materials and Methods." NT = not tested.

[c] AKR or C57BL/KsJ cell groups engrafted to each recipient stroma produced a significantly greater No. of granulocytes than N:NIH(S), C3H/HeJ, C57BL/6J, or C57BL/10J stem cells engrafted to the same groups of stroma ($P < 0.05$).

the longevity of hematopoiesis in a continuous marrow culture system that involves use of a single inoculum of bone marrow in 10^{-5} *M* hydrocortisone. Longevity of production of GM-CFU$_c$ and neutrophilic granulocytes did not correlate with *H-2* haplotype, production of basophil–mast cells, persistence of adherent adipocytes, or cumulative number of NA cells produced during the initial 8 weeks. The present studies did not attempt to correlate longevity of granulopoiesis with production of pluripotential, erythroid, megakaryocytic, or lymphoid CFU$_c$. Significant differences among strains may also be detected when these data are collected. Cultures from each strain were tested for replication of endogenous retrovirus. Cultures from those strains releasing high levels of N-tropic virus, including AKR/J, NZW, DBA/2J, C7BL/KsJ, and C58/J, were those with the greatest longevity; however, lower levels of N-tropic virus were also detectably released by cultures from the following strains that showed a significantly shorter duration of granulopoiesis: BALB/cJ, CBA/J, and C57BL/6J. Still other strains known to contain an endogenous N-tropic virus (e.g., RF/J, C57BR/cdJ, and SWR/J) (*7*) did not release detectable levels of virus despite identical culture methods.

An explanation for the significant differences in longevity of AKR/J long-term marrow cultures (that generated granulocytes in excess of 58 wk) and HRS/J marrow cultures (that produced granulocytes for 12 wk) was approached through several genetic and mixing experiments. The differences were not attributable to our use of FCS and hydrocortisone, since similar differences were detected if cultures were established in a "special" lot of horse serum that supports hematopoiesis with no added corticosteroid (*33*).

To determine whether genetic factors in the adherent stromal cell and/or NA hematopoietic stem cell compartment determined longevity of granulopoiesis, we transferred NA cells from 8-week-old AKR/J or C57BL/KsJ cultures to purified stromal cell cultures of the same or other strains with a shorter duration of granulopoiesis. These experiments indicated that the genotype of the NA AKR/J or C57BL/KsJ hematopoietic cells stimulated a significantly longer duration of granulopoiesis following engraftment of these cells to stromal cultures of short-duration strains (C3H/HeJ or C57BL/6J) compared to that observed following engraftment of hematopoietic stem cells from C3H/HeJ or C57BL/6J cultures to their syngeneic stromas. Furthermore, AKR/J stromal cultures did not confer greater longevity to engrafted C3H/HeJ or C57BL/6J hematopoietic stem cells. These data indicate that a factor in the hematopoietic stem cell compartment of AKR/J or C57BL/KsJ cultures determined longevity. Whether this factor is replication of the N-tropic endogenous virus is not yet known.

There are a number of possible interpretations of the data showing correlation of retrovirus replication with increased longevity of hematopoiesis in vitro. Limited hematopoiesis in marrow cultures of some strains may be due to an inhibitory effect of their adherent stromal cells, and retrovirus replication may block the synthesis of an inhibitor. The failure of virus-positive AKR/J stromal cultures to increase the longevity of hematopoiesis by added C3H/HeJ or C57BL/6J stem cells argues against this mechanism. Alternatively, retrovirus replication may stimulate adherent stromal cells to produce a growth factor for early hematopoietic progenitor cells. Evidence in support of such stimulation comes from data showing that retrovirus infection of bone marrow stromal cells results in elevated production of a CSF that is active for macrophage progenitor cells (*12*). Other such molecules might be induced by virus replication, and genetic factors might determine stem cell response to this factor.

WEHI-3 DCM-dependent cell lines derived from NA cells removed from marrow cultures showed a range of morphological, biological, and biochemical properties with differences persisting after cloning in some of the lines and in others in the separation of multiple subclones (*6*). While most clonal lines from most strains demonstrated predominantly neutrophilic granulocyte or macrophage differentiation capacity, several cloned lines persistently produced 1–

20% toluidine blue-positive mast cells, and others were purely mast cell–basophil. WEHI-3 DCM-dependent cultures obtained from one experiment with C57BL/6JUt and B6.S marrow cultures contained multipotential stem cell populations including those capable of forming erythroid, GM, and mast cell colonies (Humphries K, Eaves CG, Greenberger JS: Manuscript in preparation). Whether a single protein or multiple factors produced by the WEHI-3 cell line or found in concanavalin A spleen conditioned medium stimulate each of the cell phenotypes found in these cell lines (mast cell, granulocyte progenitor, and multipotential progenitor) is not yet known.

Some clonal cell lines derived from virus-positive marrow cultures maintained in WEHI-3 DCM continued to release ecotropic virus, whereas other cell lines from virus-positive primary cultures were observed to be virus-negative (*6, 8*). Thus induction of endogenous virus and persistent replication of either that induced virus or an infecting exogenous virus may occur through different mechanisms in bone marrow cultures. Divergence of mechanisms for induction and persistence of mouse retrovirus replication has been demonstrated with embryo fibroblast lines treated with 5-iodo-2′-deoxyuridine (*34*) and with lipopolysaccharide induction of virus from B-lymphocytes (*35*). None of the spontaneously generated cell lines tested produces detectable leukemia in vivo; however, further studies are required to explain elevated peripheral blood counts that were seen in mice given C57BL/KsJ cell lines, and cell lines from other strains remain to be tested.

The present studies indicate that necessary interactions between adherent and NA cell populations in the hematopoietic microenvironment of long-term bone marrow cultures vary significantly among mouse strains. These variations occur over a much broader spectrum than that initially ascribed to mutational defects in specific strains (*36, 37*) and may be attributed in part to the effect of retrovirus replication or other forms of chronic in vitro stimulation of the adherent cell compartment of the cultures (*38*). While the system appears to be complicated, understanding the mechanism by which bone marrow cultures regulate the longevity of hematopoietic stem cells should provide insight into our understanding of genetic and environmentally altered diseases of the bone marrow.

Effects of Dietary Lipids on Lactogenic Hormone Receptor Binding in Rat Mammary Tumors[1, 2, 3, 4]

William T. Cave, Jr.,[5] *and* **Marsha J. Erickson-Lucas**[5, 6]

ABSTRACT—Both epidemiologic studies in humans and experiments in laboratory animals have indicated that high-fat (HF) diets promote mammary tumor growth; however, the biochemical mechanisms responsible for this accelerated tumor growth are poorly understood; thus this study was designed to determine whether diet-induced alterations in the lipid composition of mammary tumor cell membranes were associated with differences in lactogenic hormone binding capacity. Mammary tumors were induced with *N*-methyl-*N*-nitrosourea in 50-day-old female inbred Buffalo rats that were maintained on either HF or low-fat (LF) diets composed of either 20% corn oil or 0.5% corn oil, respectively. The microsome-membrane fractions of these tumors were then analyzed for specific lactogenic hormone binding with the use of ^{125}I-labeled human growth hormone. Methylated extracts of these same membrane fractions were also subjected to gas–liquid chromatography. Our results demonstrated that the mammary tumor membranes of the HF group did have a significantly greater lactogenic binding capacity than those of the LF group and that these differences in hormone binding were accompanied by significant alterations in the membrane qualitative fatty acid profiles of each group. Therefore, one way in which dietary lipids may be able to influence mammary tumor growth is by modification of the lactogenic hormone binding capacity of tumor cell membranes.—JNCI 1982; 68:319–324.

In recent years, much evidence has accumulated that indicates that dietary lipids can influence the development of breast cancer. Data from epidemiologic surveys, for example, have revealed that human populations maintained on HF diets have a selectively increased mortality from breast cancer (*2*); prospective studies with laboratory animals have repeatedly documented that HF diets accelerate the growth rates of both spontaneous and carcinogen-induced tumors (*3–7*).

Very little is known, however, about the specific biologic mechanisms responsible for this lipid-dependent enhancement of mammary tumor growth. All that can be stated at present is that these dietary lipid effects are closely linked temporally to events occurring after tumor initiation (*8*) and that they require the presence of certain hormones such as prolactin and estrogen for their maximal expression (*4, 9*). Some investigators have postulated that these facts indicate that dietary fats can promote mammary tumor growth by modifying the normal relationship that usually exists between the initiated tumor cells and their hormonal environment (*2*); but to date how these hormone–tumor cell alterations occur has not been precisely defined.

One recently proposed hypothesis on this subject is that lipids, particularly polyunsaturated lipids, may be able to alter the physiologic activities of certain membrane-associated hormone receptors by changing the structural composition of the tumor cell membranes (*10*). This study was designed to experimentally evaluate this possibility. Its specific objectives were to establish whether quantitative changes in dietary fat could alter the lactogenic binding capacity of mammary tumor cells and, if so, to determine whether there were any particular qualitative differences in membrane lipid composition associated with these hormone receptor alterations.

METHODS AND MATERIALS

Treatment groups.—Female inbred Buffalo rats (Simonsen Laboratories, Gilroy, Calif.), 44 days old, were randomly divided into 2 groups. Group 1 was fed an LF diet containing 0.5% corn oil, while group 2 was fed an HF diet containing 20% corn oil. The specific composition of these diets (table 1) was closely patterned after previously established experimental models (*7, 8, 11*). Both diets had an equivalent ratio of protein calories to total calories.

Tumor induction.—When the rats were 51 days of age, mammary tumors were induced following the methods of Gullino et al. (*12*). MNU (K & K Laboratories, Plainview, N.Y.) was dissolved in water (10 mg/ml) and administered iv to the rats (5 mg/100 g body wt) with subsequent injections 4 and 8 weeks later. All animals were maintained under identical laboratory conditions and the developing tumors were measured weekly. When each animal's tumor reached a size of approximately 1–2 cm in diameter, the

TABLE 1.—*Diet composition*

Component	LF diet	HF diet
Corn oil (100% pure; vitamin free)	5 g/kg	200 g/kg
Casein (vitamin free)	180 g/kg	230 g/kg
Sucrose	220 g/kg	145 g/kg
Dextrose	260 g/kg	175 g/kg
Dextrin	260 g/kg	175 g/kg
Rogers Harper vitamin mix	5 g/kg	5 g/kg
Rogers Harper salt mix	50 g/kg	50 g/kg
Vitamin B_{12} (10 μg/ml water)	5 ml/kg	5 ml/kg
Choline (0.20 g/ml water)	15 ml/kg	15 ml/kg

animal was killed unanesthetized by cervical transection early in the day during diestrus. Immediately afterward, an autopsy was performed and samples of tumor and liver tissue were snap frozen in liquid nitrogen and stored at −80°C.

Subcellular fractionation.—The frozen samples were initially powdered in a pulverizer (Thermovac Industries Corp., St. Copiague, N.Y.) and then homogenized in a tissumizer (Tekmar Co., Cincinnati, Ohio) with 6 volumes (wt/vol) of TM buffer (pH 7.55). After homogenization, the samples were separated into subfractions by an initial centrifugation at 15,000×*g* for 20 minutes and then a subsequent spin of the supernatant at 190,000×*g* for 60 minutes. This 190,000×*g* pellet (microsome-membrane fraction) was then divided into two portions. One portion was saved for lipid analysis by storage at −80°C in a gaseous nitrogen atmosphere, while the remainder was resuspended in TM buffer and used for receptor analysis.

Hormone iodination.—Carrier-free ^{125}I was obtained from Amersham Corp., Arlington Heights, Ill., and hGH-I-1 and oPRL-I-1 were obtained from the National Institute of Arthritis, Diabetes, and Digestive and Kidney Diseases, Bethesda, Md. Both of these hormones were iodinated with lactoperoxidase according to the general methodology of Thorell and Johansson (*13*), but with the use of an immobilized preparation of lactoperoxidase and glucose oxidase (Enzymobead; BioRad Laboratories, Richmond, Calif.). The iodinated hormone was separated from the free ^{125}I on a Sephadex G-25 column with a 0.01-*M* borate buffer (pH 8.0) for elution. The specific activity of the iodinated hormones ranged from 90 to 130 μCi/μg.

Hormone binding assays.—We measured the hormone binding in these studies by using the previously established methodology of Posner et al. (*14*), Posner (*15*), and Shiu and Friesen (*16*). ^{125}I-labeled hormone was incubated with 140 μg of the microsome-membrane protein in a final volume of 0.5 ml containing 0.2% BSA–TM buffer (pH 7.55) for 22 hours at 24°C. Parallel incubations were performed in the presence of excess unlabeled hormone (hGH, 2.5 μg; or oPRL, 2.5 μg) to determine nonspecific binding. The assay was terminated by the addition of 3 ml of 0.1% BSA–TM buffer, and the bound and the free-labeled hormones were separated by centrifugation as described by Posner (*15*). Specific hormone binding was calculated by subtraction of the nonspecific counts from the total radioactivity bound. Measurements of lactogenic binding capacity (^{125}I-labeled hGH) were made on the microsome-membrane fractions of both mammary tumors and liver tissues; however, due to a limited amount of tumor tissue, measurements of ^{125}I-labeled oPRL binding were made only on the hepatic tissue.

Fatty acid extraction, hydrolysis, and methylation.—Lipid extraction was performed according to the methods of Folch et al. (*17*). Approximately 10–30 mg of microsomal membrane fraction was suspended in 2.0 ml of methanol containing 1 mg/100 ml (wt/vol) butylated hydroxytoluene and mixed with 2.0 ml of chloroform. After sitting in this mixture overnight at 4°C in a nitrogen atmosphere, the samples were centrifuged at 1,100×*g* for 5 minutes. The supernatant was removed and then mixed with 2.0 ml of chloroform and 1.5 ml of 0.74% aqueous KCl. After centrifugation the bottom layer was dried down under nitrogen. The residue was then resolubilized in 2 ml of 3 *N* HCl in methanol and incubated in a water bath at 75°C for 2 hours. After incubation, the methylated lipids were washed with 2 ml of water and 4 ml of *n*-hexane. The resultant supernatant was then mixed with 0.1% Na_2CO_3; after a further centrifugation step, the upper layer was removed and stored under gaseous nitrogen at 4°C until ready to be analyzed by gas-liquid chromatography.

Qualitative fatty acid analysis—At the time of final analysis, the stored methylated lipids were dried down under gaseous nitrogen and redissolved in 50 μl of *n*-hexane. Two microliters of this solution was then analyzed in a gas chromatograph (Hewlett-Packard 5830A) with the use of a 6-foot glass column packed with 10% SP-2330 on a 100/120 chromosorb W acid-washed support (Supelco, Inc., Bellefonte, Pa.). The retention times of the individual fatty acids and the integrated areas under each peak were obtained directly from the computer associated with the instrument. We determined the identity of the specific peaks by comparing them to known standards (Supelco, Inc. and Sigma Chemical Co., St. Louis, Mo.) run at the time of the assay.

Data analysis.—All results are presented as the mean plus or minus the standard error of the mean. The data were evaluated statistically by analysis of variance with a Hewlett-Packard Model 9830A desk top computer and its program.

RESULTS

Autopsy data.—The autopsy findings on the animals from this study are presented in table 2. Although we observed a slight but significant difference in the body weights of the 2 groups, we saw no clinical or autopsy evidence (e.g., scaly skin, roughened hair coat, or necrosis of the tail) to suggest that this was due to any dietary deficiency in the LF group. There were no statistical differences between the liver weights of the 2 groups.

All animals in both groups developed mammary tumors; however, the animals given HF diets had more tumors per animal than did the animals given LF diets. Furthermore, the animals given HF diets, despite a significantly earlier mean age at death, had a tumor burden that was equivalent, if not slightly greater, than that of the animals given LF diets. This observation indicated that the animals given HF diets had required significantly less time than did the animals given LF diets to develop a similar tumor burden. A graphic illustration of these relationships is presented in text-figure 1.

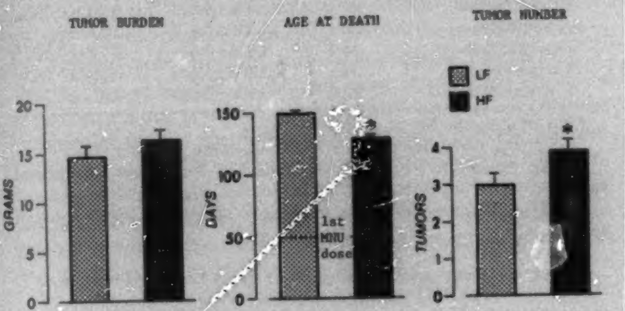
TABLE 2.—*Mammary carcinogenesis MNU-treated rats on HF and LF diets*

Diet	No. of rats	Age at death, days[a]	Body weight, g[a]	Liver weight, g[a]	Tumor No.[a]	Tumor burden, g[a]
LF	19	150.5±2.9[b]	209.3±3.4[c]	8.54±0.23	3.0±0.3[b]	14.3±2.2
HF	19	129.5±3.2	226.6±2.9	8.69±0.28	3.9±0.3	17.23±2.0

[a] Values are means ± SE.

[b] Difference from HF group significant at $P<0.05$ by analysis of variance.

[c] Difference from HF group significant at $P<0.01$ by analysis of variance.

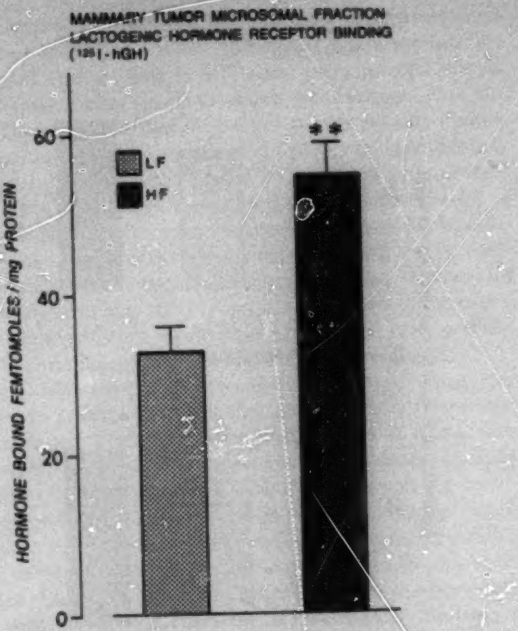


TEXT-FIGURE 1.—Autopsy findings on the animals used in this study. Each group consists of data from 19 animals. *Bar graphs* depict the means±SE for each group. *Single asterisks* indicate that the differences between the 2 groups was significant at $P<0.05$ by analysis of variance.

Mammary tumor membrane hormone binding data.—The results of the studies on the binding of ^{125}I-labeled hGH to the mammary tumor microsome-membrane fractions of the 2 treatment groups are presented in text-figure 2. This text-figure clearly shows that the binding capacity of the HF samples (54.8±4.0 fmol/mg protein) was significantly greater ($P<0.01$) than that of the LF samples (32.8±3.2 fmol/mg protein).

Liver membrane hormone binding data.—The results of comparable studies measuring the binding of ^{125}I-labeled hGH to the microsome-membrane fractions of hepatic tissue are presented in text-figure 3A. As this text-figure indicates, the lactogenic hormone binding capacities of the hepatic membranes of the HF group (92.9±9.4 fmol/mg protein) were also greater than those of the LF group (75.4±6.2 fmol/mg protein). These differences in hepatic binding, however, were not quite great enough to be statistically significant.

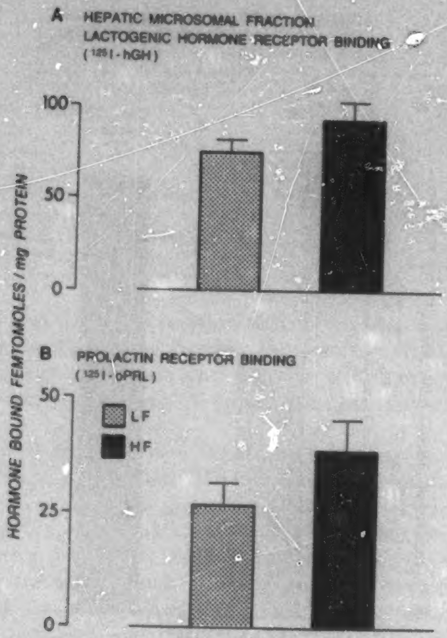
An almost identical pattern of binding was observed when these same hepatic microsome-membrane fractions were incubated with ^{125}I-labeled oPRL (text-fig. 3B). Although the differences between the 2 groups again failed to reach statistical significance, the HF samples persistently demonstrated a greater binding capacity for the ^{125}I-labeled oPRL (38.8±6.7 fmol/mg protein) than the LF samples (26.7±5.0 fmol/mg protein). In addition, despite the fact that the absolute amount of the ^{125}I-labeled oPRL bound to the hepatic membrane fraction was somewhat less than that observed for the ^{125}I-labeled hGH, the actual measured differences in hormone binding capacity between the HF and LF samples were almost the same, regardless of which hormone binding assay results were used. This observation would appear to indicate that the differences observed in hepatic ^{125}I-labeled hGH binding can be attributed almost completely to changes in prolactin receptor binding as measured by ^{125}I-labeled oPRL.



TEXT-FIGURE 2.—Lactogenic hormone binding capacity of mammary tumor microsomes as measured with ^{125}I-labeled hGH. Data from the LF diet group represent the results of determinations made on tumors from 12 individual animals, whereas data from the HF diet group represent the results of determinations made on tumors from 11 individual animals. *Bar graphs* depict the means±SE values for each diet group. *Double asterisk* indicates that the difference between the 2 groups is statistically significant at $P<0.01$ by analysis of variance.

Mammary tumor fatty acid profile.—The distribution profiles of the fatty acids extracted from the tumor microsome-membrane fractions are represented in table 3. Several significant differences were readily detectable between the 2 groups. In general, the HF samples had significantly greater percentages of their total lipids in the form of the polyunsaturated fatty acids linoleic acid (18:2) and ecosatrienoic acid (20:3) than the LF group and significantly lower percentages of the saturated fatty acids *n*-pentadecanoic acid (15:0), palmitic acid (16:0), palmitoleic acid (16:1), stearic acid (18:0), and oleic acid (18:1). The only exception to this trend was the slight but significant decrease in the percentage of arachidonic acid (20:4) observed in the HF samples.

Hepatic fatty acid profile.—Comparable data outlining the distribution profile of the fatty acids in the hepatic microsome-membrane fraction are presented in table 4. Very similar to the results obtained from the analysis of the tumor lipid samples, the hepatic HF samples also had significantly less of their total lipid in the form of the more saturated fatty acids—palmitic acid (16:0), palmitoleic acid (16:1), and oleic acid (18:1)—than the LF samples. There were some additional differences that were not noted in the tumor samples, such as significantly greater percentages of stearic



TEXT-FIGURE 3.—A) *Bar graphs* depict the mean plus or minus standard error of the lactogenic binding capacities of hepatic microsomes as measured with ^{125}I-labeled hGH. Data from the LF diet group represent determinations made on livers from 18 animals, whereas data from the HF diet group represent determinations made on 17 animals. B) *Bar graphs* depict the means±SE of the binding capacities of hepatic microsomes for ^{125}I-labeled oPRL. The number of livers sampled in each group are the same as noted in 3A.

acid (18:0), arachidonic acid (20:4), docosatetranoic acid (22:4), and docosahexanoic acid (22:6) in the HF samples and a significantly lower percentage of myristic acid (14:0).

DISCUSSION

The ability of dietary fat to enhance mammary tumor growth in laboratory animals was initially documented by Tannenbaum (*3*) in 1942 when he reported that DBA mice fed an HF diet had an increased incidence of spontaneous mammary tumors. Since then many others have confirmed this relationship in rodents, not only for spontaneous mammary tumors but also for carcinogen-induced and transplanted mammary tumors (*4–7, 18*). In the present experiments, this effect of dietary lipids on mammary tumor growth was reflected in the finding that the animals given HF diets had more tumors per animal and a faster tumor growth rate than the animals given LF diets.

The scientific importance of this relationship rests in the fact that it is uniquely restricted to dietary lipids and is independent of caloric intake. Animals on HF diets have been consistently shown to have greater mammary tumor growth rates than pair-fed animals on equal caloric LF diets (*19, 20*). Such effects have not been observed to occur as a result of comparable variations in any of the other dietary components such as protein, vitamins, or minerals above those required for normal maintenance (*21*).

Precisely how dietary lipids specifically enhance mammary tumor growth is poorly understood. It has been documented that qualitative and quantitative differences in dietary lipids can significantly modify the biochemical composition of mammary tumor cells (*18*), but to what extent these changes in tumor lipid composition can be directly correlated with the enhanced tumor growth observed is still unclear. For example, even though it has been shown that some tumor cell lines do increase their growth rates in response to dietary increases in linoleic acid, it has not been possible to define any universal correlation between the precise amount of linoleic acid in a tumor and its specific growth rate (*22*). Therefore, most investigators have concluded that if differences in the lipid composition of mammary tumor cells do affect tumor growth, they must do so in a relatively complex fashion. Certainly, the evidence would indicate that other factors such as the genetic character of the cell line and the physiologic characteristics of the host can also significantly influence the final rate of lipid-dependent mammary tumor growth.

Our knowledge of the physiologic parameters of the host, which are most important in facilitating lipid-dependent mammary tumor growth, is still rather limited. The data that have been accumulated, however, strongly suggest that the hormonal environment is especially important. Wicha et al. (*10*), for example, have shown quite clearly that the growth rates of primary cultures of 7,12-dimethylbenz[*a*]-anthracene-induced rat mammary tumor cells are much greater when specific hormones (i.e., 17β-estradiol, prolactin, progesterone, insulin, and hydrocortisone) are added to the media with oleic or linoleic acid than when either of these fatty acids is added alone. Which hormones are most influential in this lipid-dependent growth process has not been unequivocally resolved, but data showing that prolactin-inhibiting drugs, estrogen antagonists, and ovariectomy can greatly reduce or totally abolish this lipid-dependent growth process have made it clear that prolactin and estrogen must be critically involved (*4, 9*).

In the past, our concepts of how prolactin might facilitate lipid-dependent mammary tumor growth have been very speculative. It was proposed initially that dietary lipids might be able to directly stimulate pituitary gland production (*23*), but subsequent experimental studies revealed that animals on HF diets and with accelerated mammary tumor growth do not have elevated basal serum prolactin levels and their pituitary glands do not synthesize increased quantities of prolactin in vitro (*4*). Moreover, other studies (*24*) have shown that even when the serum prolactin levels of animals on LF and HF diets are increased to equally high levels by hypothalamic lesions, a difference in mammary tumor growth rates persists. Therefore, it has remained necessary to continue to search for alternate possible mechanisms of prolactin–lipid interaction in mammary tumorigenesis.

We believe that our results have now resolved some of this previous uncertainty by providing substantial evidence in favor of the hypothesis that dietary fats can alter the sensitivity of mammary tumor cells to prolactin. Our data show very clearly that the tumor membranes of the animals given HF diets have significantly greater lactogenic hormone binding capacities than those of the animals given LF diets; and since it is well recognized that prolactin initiates its hormonal action via such membrane receptors (*25*), it is highly probable that, at any comparable physiologic prolactin level, there would be a greater mammotrophic stimulation of the tumor cells from animals given HF diets than from animals given LF diets. We cannot state conclusively, at this time, whether these differences in hormone binding are due to generalized alterations in the total mammary tumor cell population or selective changes in a specific subpopulation of tumor cells; but the observation that dietary lipids can induce similar, though less significant, changes in the hormone binding capacities of liver cells suggests that modifications in prolactin responsiveness very likely occur in a variety of target cells as well.

Our perception of the biochemical mechanisms responsible for these alterations in the lactogenic hormone binding capacities of tumor cells is still very incomplete. Several recent investigations, however, have pointed out that the structural changes induced in the cell membranes by dietary lipids, particularly polyunsaturated lipids, can significantly increase membrane fluidity (*26, 27*). Such changes in membrane fluidity have been postulated to be great enough to regulate the accessibility of membrane receptors to circulating hormones. Our results would certainly seem very compatible with this concept. They show that the tumor and liver membranes from the HF group had both the greatest degree of unsaturation evident in their fatty acid profiles and the highest lactogenic hormone binding capacities.

We conclude, therefore, that our experimental results not only confirm previous reports that dietary lipid alterations can significantly affect the fatty acid profiles of mammary tumor membranes but also show that such changes in lipid composition can be associated with differences in the lactogenic hormone binding capacities of these tumor membranes. Certainly, further studies will be needed to establish whether these changes in binding capacity are functionally significant; but if this can be accomplished, it would strongly suggest that one way dietary lipids can modify mammary tumor growth is by inducing changes in the lactogenic hormone binding capacities of tumor cell membranes.

Lipopolysaccharide and Pristane-Induced Peritoneal Exudate Requirements for Plasma Tumor Cell Colony Formation[1,2,3]

Micsunica Platica,[4] Catherine Bojko,[4] Radu Clincea,[4] *and* Vincent Hollander[4,5,6]

ABSTRACT—The role for lipopolysaccharide (LPS) and a pristane-induced peritoneal exudate (PIPE) on the in vitro development of murine plasmacytoma was studied. MOPC-315 cell suspensions showed little tendency for colony formation in a soft agar culture medium. Additions of LPS and PIPE were required for maximal colony formation. The LPS effect was dose-dependent down to nanogram quantities. PIPE prepared from inbred strains of mice not susceptible to pristane-induced plasmacytoma (DBA/2) or from normal peritoneal washings was ineffective. PIPE activity was radioresistant and not transferable by cell-free conditioned medium. Three strains of transplantable plasmacytomas showed colony formation stimulation by LPS plus PIPE, but LPS and PIPE were ineffective with lymphosarcoma P1798.—JNCI 1982; 68:325-328.

Soft agar techniques are widely used for cloning of normal hematopoietic and myeloid leukemia cells in mice and humans (*1–9*). Colony formation can be potentiated by various factors (*1, 5, 10–17*). When cultured in semisolid agar, some myeloma cell lines also have the ability to form colonies (*18–23*). For these reasons, the soft agar technique was selected to assess the role of LPS and PIPE in vitro.

Administration ip of mineral oil and/or related compounds induces plasmacytomas in inbred BALB/c mice. Work done in our laboratory suggested that LPS and PIPE play a role in the pathogenesis of such plasmacytomas (*24–26*). Now we report that PIPE along with LPS induces colony formation by transplantable plasma tumor cell lines in soft agar.

MATERIALS AND METHODS

Mice.—Female inbred BALB/c and DBA/2 mice 6–8 weeks old (Simonsen Laboratories, Gilroy, Calif.) were used.

Tumors.—MOPC-315, a transplantable plasma tumor cell line, was transplanted and carried as previously described (*27*). MPC-11 (supplied by Dr. Susan Zolla, Veterans Administration Hospital, New York, N.Y.) and MOPC-104 (obtained from The Salk Institute, San Diego, Calif.) were transplanted and prepared as described for MOPC-315. P1798, a murine lymphosarcoma induced in BALB/c mice by diethylstilboestrol–cortisol, was obtained from Dr. John Stevens (American Cancer Society, New York, N.Y.). It was prepared and transplanted by the method described by Stevens et al. (*28*) with slight modifications.

Preparation of PIPE and NPW.—PIPE and NPW were prepared as described previously (*26*). In some experiments the cellular component of PIPE or NPW was destroyed by repetitive freezing and thawing. The procedure was repeated until 100% dead cells were found by the trypan blue exclusion test. In other experiments the PIPE was irradiated (2,500 rad/1×10^7 PIPE cells). In some experiments the PIPE-conditioned medium was used; 1.5×10^7 cells were cultured in 2 ml of McCoy's 5-A medium with and without LPS. The cultures were collected at 4, 7, and 10 days after plating and centrifuged at $504\times g$ for 10 minutes, and the supernatant representing PIPE-conditioned medium was used in colony assay.

LPS preparation.—LPS *Escherichia coli* 055:B5 was obtained from Difco Laboratories, Detroit, Mich. Dilutions of LPS were made in LPS-free 0.85% NaCl.

Karyotypic analysis.—The method of Worton and Duff (*29*) was used for karyotypic analysis of cells in colonies.

Assay for colony-stimulating activity.—A slightly modified method from that described by Kincade et al. (*30*) for B-cell cloning was used. All cultures were done in plastic petri dishes 35×10 mm (Corning Glass Works, Corning, N.Y.). The culture medium was a 9:1 mixture of enriched McCoy's 5-A medium (M.A. Bioproducts, Walkersville, Md.) supplemented with 10% heat-inactivated fetal calf serum and 0.3% agar (Difco Laboratories). Triplicate cultures were prepared; each contained 1×10^5 plasma tumor cells (MOPC-315, MPC-11, or MOPC-104) or 1×10^4 P1798 cells in 1 ml agar medium. Various amounts of PIPE, NPW (collected from BALB/c or DBA/2 mice), PIPE-conditioned medium, or LPS were added to each culture from the beginning unless otherwise indicated. The PIPE, NPW, or PIPE-conditioned medium was added to the agar medium containing the tumor cells; then 1 ml of this mixture was pipetted into culture dishes with or without LPS. After testing a wide range of PIPE cell numbers (5×10^4–5×10^6 cells/plate) and LPS doses ranging from 5 ng to 125 µg/plate, we found that 1–2×10^5 PIPE cells in the presence of 50 µg *E. coli* LPS were

optimal for PCT colony formation. The plates were incubated at 37°C in a fully humidified atmosphere of 7% CO_2 in air. Colonies were counted 6–7 days after plating by use of an inverted microscope. Only aggregates of more than 20 cells were scored as colonies. Plating efficiency was defined as (number of colonies/number of cells per plate)×100. The cells that grew in colonies were identified as typical plasma tumor cells by morphology, karyotype analysis (only for MOPC-315), and their ability to induce typical plasmacytomas when transplanted sc into BALB/c mice. MOPC-315 cells are polyploid (modal number, 66) with a submetacentric marker; metaphase preparations from cells that develop colonies were also polyploid (modal number, 66; range, 62–70) with one submetacentric marker.

RESULTS

Table 1 shows that MOPC-315 cells, regardless of the number used per culture, produced no colonies when these cells were cultured alone in soft agar under conditions described above. When given independently, neither LPS (doses ranging from 5 ng to 125 μg/plate) nor PIPE collected from BALB/c mice 2 months after pristane administration (5×10^4–5×10^6 cells/plate) stimulated MOPC-315 colony formation. In contrast, PIPE plus LPS consistently produced a number of colonies of typical plasmacytomas. Within each experiment we ran a control containing PIPE alone, cultured under the same conditions as those described in "Materials and Methods" but without PCT. Only a very few isolated cells could be seen after the PIPE was kept in agar–McCoy's 5-A medium for 6 days. No colonies were observed. Similar results were obtained with PIPE collected 3 days after pristane inoculation into BALB/c mice (data not shown).

Either alone or combined with different amounts of LPS, PIPE collected from DBA/2 mice, a strain resistant to plasmacytoma induction, was unable to induce colonies. When tested alone or with LPS, NPW prepared from strains of mice resistant (DBA/2) or susceptible (BALB/c) to plasmacytomas, containing amounts of cells similar to those found to be active in PIPE, were also ineffective on MOPC-315 colony formation. The effect of delayed addition of LPS or PIPE on colony formation by PCT was also evaluated. When PCT cells were incubated in semisolid medium in the presence of LPS and PIPE was added 24 hours later, almost no colonies were obtained. Similar results were obtained when LPS was added 24 hours after the beginning of the experiment.

From our present results it seems that PIPE and LPS activities show at least some specificity. PIPE alone or combined with LPS did not stimulate the colony formation by P1798, a murine lymphosarcoma. In contrast, PIPE and LPS potentiated the colony formation by MOPC-315, MPC-11, and MOPC-104, three transplantable plasma tumor cell lines. No colonies were found in the presence of either LPS or PIPE alone (table 2) except for MOPC-104, which has the ability to form colonies even in the absence of PIPE or LPS, but the number of colonies formed was greatly increased by the presence of PIPE plus LPS.

When PIPE was fractionated by centrifugation at 1,080×*g* for 10 minutes into a supernatant and pellet, a highly stimulatory effect on MOPC-315 colony production was seen with the pellet fraction. Almost no effect was obtained with the supernatant. Repetitive freezing and thawing of PIPE completely abolished the ability to induce colonies in soft agar, whereas irradiation (2,500 rad/1×10^7 PIPE cells) had no diminishing effect on the capacity of PIPE to stimulate the colony formation. PIPE-conditioned medium (over a wide concentration range) was unable to induce MOPC-315 colony formation whether or not it was obtained from PIPE cultured in the presence of LPS and plated with or without LPS (table 3).

Text-figure 1 shows that the MOPC-315 colony formation in the presence of LPS and PIPE was LPS dose-dependent. A linear relationship between the log of LPS concentration and the number of colonies formed was observed. The correlation coefficient (0.93) and 95% confidence limits are

TABLE 1.—*Effect of PIPE plus LPS on MOPC-315 colony formation*

Group No.	Tumor used[a]	Material added[b]	Mean No. of colonies[c]	Plating efficiency
1	MOPC-315	None	3±2	0.003
2	MOPC-315	LPS	5±4	0.005
3	MOPC-315	PIPE[d]	25±4	0.025
4	MOPC-315	PIPE + LPS	1,065±250	1.06
5	MOPC-315	PIPE + saline	35±10	0.035
6	None	PIPE[e]	0	—

[a] MOPC-315 cells were plated at 1×10^5 cells/culture, except in group 1 where a range of cell numbers of 1×10^4–5×10^6 cells/plate was used. Colonies were scored after 6 days of culture.

[b] PIPE was collected 2 mo after ip administration of pristane to BALB/c mice.

[c] Mean of triplicate cultures ± SD. Four experiments with similar results were done.

[d] In 2 of 20 experiments PIPE alone gave similar colony counts to PIPE plus LPS.

[e] PIPE was cultured as described in "Materials and Methods" but without plasma tumor cells added.

TABLE 2.—*Effect of PIPE and LPS on MPC-11, MOPC-104, and P1798 colony formation*

Group No.	Tumor used[a]	Material added[b]	Mean No. of colonies[c]
1	MPC-11	None	15±10
2	MPC-11	LPS	25±5
3	MPC-11	PIPE	32±16
4	MPC-11	LPS + PIPE	890±110
5	MOPC-104	None	83±12
6	MOPC-104	LPS	125±15
7	MOPC-104	PIPE	206±52
8	MOPC-104	LPS + PIPE	1,100±180
9	P1798	None	2±3
10	P1798	LPS[d]	5±2
11	P1798	PIPE	4±3
12	P1798	LPS[d] + PIPE	6±5

[a] MPC-11 and MOPC-104 were plated at 1×10^5 cells/culture. P1798 was plated at 1×10^4 cells/culture.

[b] PIPE was collected 2 mo after ip administration of pristane to BALB/c mice.

[c] Mean of triplicate cultures ± SD. Three experiments with similar results were done.

[d] LPS dose range: 5 ng–50 μg/plate.

shown. The text-figure also shows that nanogram doses of LPS have potentiating effects on MOPC-315 colony formation.

TABLE 3.—*Effect of LPS, PIPE fractions, irradiated and freeze-thaw-treated PIPE, or PIPE-conditioned medium on MOPC-315 colony formation*[a]

Group No.	Material added[b]	Mean No. of colonies[c]
1	None	6±3
2	Supernatant[d] + LPS	18±7
3	Pellet[d] + LPS	830±53

5	Freeze-thaw-treated PIPE + LPS	28±5
6	PIPE-conditioned medium[e] + LPS	13±4
7	PIPE-conditioned medium[f] + LPS	20±5
8	PIPE + LPS[g]	35±10
9	PIPE[g] + LPS	20±5

[a] All cultures contained 1×10^5 MOPC-315 cells.

[b] PIPE was collected 2 mo after ip administration of pristane to BALB/c mice. No colonies were obtained in the absence of LPS in the experimental groups. For brevity these negative results were not presented.

[c] Mean of triplicate cultures ± SD. Three experiments with similar results were done.

[d] These fractions were obtained by centrifugation at 1,080×*g* for 10 min.

[e] PIPE was cultured in medium without LPS and processed as described in "Materials and Methods."

[f] PIPE was cultured in medium with LPS and processed as described in "Materials and Methods."

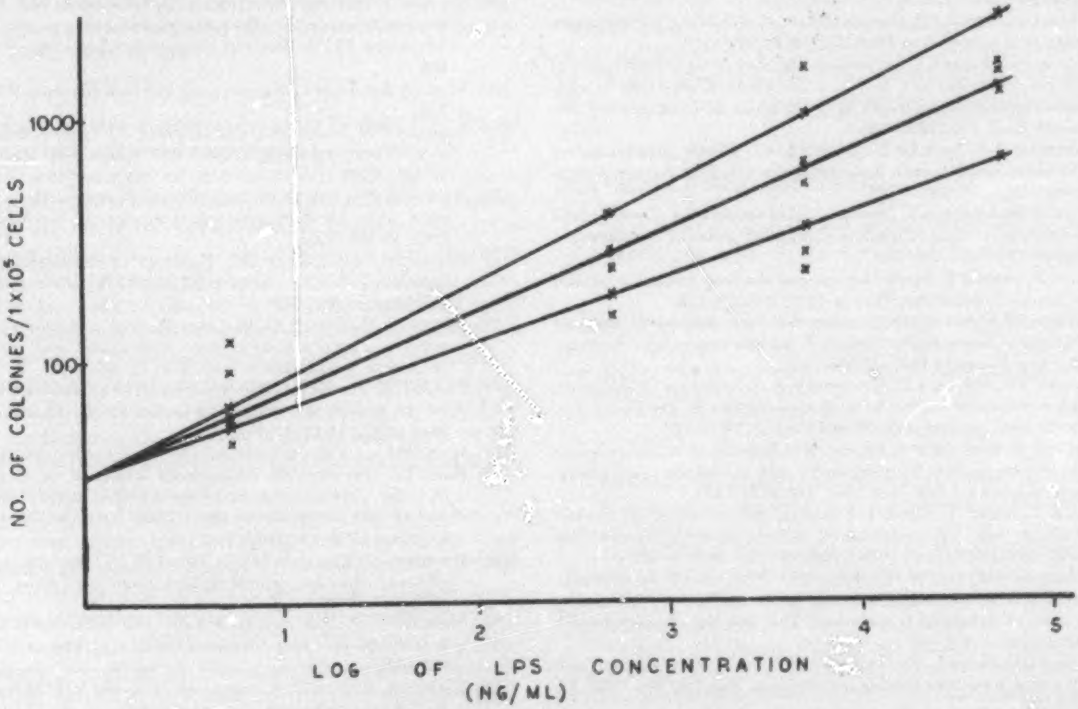
[g] This material was added 24 hr after plating.

DISCUSSION

Administration ip of mineral oil and related substances into susceptible strains of mice induced plasmacytomas after a latent period (*31, 32*).

We have presented evidence that chronic administration of LPS enhances pristane-induced tumorigenesis (*24*). Small inocula of primary plasma tumor cells are not able to transplant into new recipients unless the animals are conditioned by ip administration of pristane at least 3 days before tumor inoculation (*33, 34*). Recently, we showed that such small inocula could also be transplanted into mice pretreated with a peritoneal exudate induced by pristane in BALB/c mice (*26*).

The present work extends these earlier observations concerning the role of LPS and PIPE on the pathogenesis of PCT. With the soft agar technique, we were able to show that PIPE along with LPS consistently induced colony formation by MOPC-315, a plasma tumor cell line. Neither LPS nor PIPE alone was able to induce MOPC-315 colony production except in 2 of 20 experiments in which PIPE alone potentiated the PCT colony formation. Possibly, these two positive results were due to contamination of PIPE with LPS (*35*). The number of colonies obtained was LPS dose-dependent. LPS was effective even in nanogram dose ranges. A temporal relationship was observed. A 24-hour delay in the addition of either one of these two fractions to MOPC-315 cultures resulted in far less colony formation. These data are consistent with a synergistic role of peritoneal cells and LPS in the growth and development of PCT. PIPE and



TEXT-FIGURE 1.—LPS dose response.

LPS activities seem to be specific for plasmacytomas. The three transplantable plasma tumor cell lines studied presented colonies under the experimental conditions described, whereas no colonies were formed by the murine lymphosarcoma P1798.

The novelty of our work consists of stressing the role of nanogram amounts of LPS in the pathogenesis of PCT. Only a few reports have shown the effect of small amounts of LPS (*36–39*), and to our knowledge none have dealt with the effect of nanogram doses of LPS on plasma tumor cells. Possibly, LPS interacted with particular cells from PIPE causing them to produce or release factors stimulating PCT colony formation. However, since PIPE-conditioned medium does not stimulate colony formation, it is unlikely that the effect results from a soluble mediator produced by PIPE.

Different factors were reported as promoting PCT colony formation (*18–21*). The relationship between the colony-stimulating factor and PIPE cells stimulated by LPS and other PCT-stimulating factors described is not clear. Studies concerned with further identification of the active part of PIPE and its effect on other T- and B-cell lymphomas as well as other plasmacytomas are in progress.

Plasminogen Activator, Fibronectin, Lymphotoxin Sensitivity, and Natural Skin Reactivity Relationships to Guinea Pig Cell Tumorigenicity[1, 2]

Richard P. McCabe[3] *and* **Charles H. Evans**[3, 4]

ABSTRACT—The quantitative expression of five properties of chemical carcinogen-induced, neoplastically transformed NIH strain 2 guinea pig fibroblasts was compared in cells possessing thousandfold differences in tumorigenicity. Plasminogen activator synthesis, sensitivity to lymphotoxin inhibition of cell proliferation, and the ability to induce a natural delayed tuberculin-type skin reaction in nonimmune syngeneic guinea pigs correlated directly with the number of cells required to produce a tumor. The most tumorigenic cells (10^2-cell threshold dose) produced the most plasminogen activator, were most sensitive to lymphotoxin, and produced the greatest skin reactivity. Cells with a threshold tumor dose of 10^6–10^7 cells exhibited the lowest expression of these properties. Fibronectin incorporation into an extracellular matrix was diminished in tumorigenic cells, as was anchorage-dependent growth; but neither diminished fibronectin incorporation nor the decreased anchorage requirement correlated quantitatively with the number of cells required to produce a tumor. The present investigation indicates that plasminogen activator synthesis, sensitivity to lymphotoxin, and the capacity of tumorigenic cells to induce natural delayed-type skin reactivity are among the factors that influence initial tumor growth. Plasminogen activator, an extracellular protease, may aid in the growth and spread of tumor cells in vivo by interfering with host fibrin deposition and by inactivating other host proteins such as lymphotoxin.—JNCI 1982; 68:329–336.

One of the central objectives of tumor biology is to define the interactions between tumorigenic cells and the host during the early stages of carcinogenesis that culminate in a progressively growing tumor. Cells most efficient in tumor formation are likely to express altered characteristics that function to the advantage of these efficient cells in these interactions and distinguish them from less efficient cells. Properties that may be altered in tumorigenic cells as compared to nontumorigenic cells include protease production (*1–3*), expression of cell surface antigens (*4–6*), production of extracellular matrix components such as fibronectin (*7, 8*), and sensitivity to a variety of natural cytotoxic host effector mechanisms (*9, 10*). The question remains as to the role of the altered properties in the formation of a primary autochthonous tumor.

In vitro models of carcinogenesis, especially those that are syngeneic and adequately studied with respect to their tumor immunology and natural immune capacity, provide the opportunity for elucidation of the initial cell–host interactions which facilitate or prevent tumor growth. Previous work with a series of NIH strain 2 (2/N) guinea pig cells transformed in culture by chemical carcinogens described the development of tumorigenicity (*11*), karyologic alterations (*12*), immunogenicity (*13, 14*), sensitivity to the growth inhibitory effects of homologous lymphotoxin (*9, 15*), and ability to induce an id delayed tuberculin-like skin response in nonimmune syngeneic animals (*9*). These cells do not express detectable cell line-specific tumor rejection antigens or have the ability to induce serologic or cellular tumor-specific immunity (*13*), yet they have acquired individually distinctive susceptibilities to cytotoxicity mediated by lymphotoxin and by normal (naturally immune) syngeneic leukocytes (*10, 15*). Guinea pig cells produce plasminogen activator, and the expression of this property occurs during the process of carcinogenesis as the cells become tumorigenic (*16*). These previous investigations established the characteristic properties of this model and the reactivity of the tumorigenic cells with various immunologic effectors but did not address the interrelationship of any of the cellular properties to the ability of the cells to produce a tumor. The present study investigates the quantitative relationship of these properties to the specific tumorigenic ability of the cells. Accordingly, the quantitative expression of plasminogen activator, anchorage-independent growth, fibronectin production and incorporation, lymphotoxin sensitivity, and natural skin reactivity were assessed in five lines of tumorigenic syngeneic 2/N guinea pig cells. The expression of each of the properties was related to the distinctive tumorigenicity of each cell line as measured by its minimum tumorigenic dose.

MATERIALS AND METHODS

Cell cultures.—Table 1 lists some properties of the guinea pig fibroblasts used. Tumorigenic cell lines were selected to

TABLE 1.—*Strain 2/N guinea pig cells*

Culture designation[a]	Passages	Previous chemical treatment	Tumorigenicity[b]
2°	2–5	None	–
103	40–50	Acetone	–
106[c]	117–127	7,12-Dimethylbenz[*a*]anthracene	–
104C1	43–45	Benzo[*a*]pyrene	+
107C3	77–87	*N*-Methyl-*N*′-nitro-*N*-nitrosoguanidine	+
HM4C1	98–108	*N*-Methyl-*N*′-nitro-*N*-nitrosoguanidine	+
74C3	69–79	3-Methylcholanthrene	+
HM2C1	95–105	Diethylnitrosamine	+
L1C1[d]	24–34	Diethylnitrosamine	+

[a] Designation suffixes C1 and C3 refer to clones derived from single cells obtained from colonies growing in 0.35% agar.

[b] Tumorigenicity (+ or –) was determined by the ability of as many as 10^6 cells to produce a progressively growing tumor after sc injection into nonirradiated or gamma-irradiated 1-day-old or 4- to 6-month-old male 2/N guinea pigs (*11*), respectively. All tumorigenic cells gave rise to fibrosarcomas except L1C1, which produced a carcinoma.

[c] Cells designated 106 were derived from the same fetus as 103, 104, and 107 cells. The 106 cells exhibit the transformed colony morphology typical of tumorigenic cells but at 125 passages after carcinogen treatment remain nontumorigenic at an sc dose of 10^6 cells/animal.

[d] L1C1 is a cloned line obtained from an ascites variant of an in vivo induced guinea pig hepatocellular carcinoma (*17, 23*). L1C1 was included as a tumor cell control in some experiments. All other cell lines were derived from guinea pig fetuses and exhibit a fibroblast-like appearance (*11*).

represent a range of tumorigenic thresholds. When injected sc or id into syngeneic animals (*13, 14*) under the conditions used in this study, none of these cells induces tumor-specific immunity. Nontumorigenic control cells were selected to include short-term (culture 2°), intermediate-term (culture 103), and long-term (culture 106) passaged cells, including the carcinogen-induced, morphologically transformed but nontumorigenic (culture 106) cells. All cells were obtained from stocks preserved in liquid nitrogen, were studied within 10 passages after reintroduction into culture, and were grown in RPMI-1640 medium with 10% FBS (complete medium) at 37°C in a water-saturated atmosphere containing 5% CO_2 (*9*).

Analysis of plasminogen activator.—Plasminogen activator was assayed essentially as described by Strickland and Beers (*18*). Fibrinogen (bovine, 98% clottable protein; Calbiochem-Behring Corp., Los Angeles, Calif.) was radiolabeled by the chloramine-T method (*19*) to a specific activity of 3–6×10^5 cpm/µg. Radiolabeled fibrinogen and unlabeled fibrinogen were mixed in phosphate-saline buffer (0.68 m*M* Na_2HPO_4, 0.12 m*M* KH_2PO_4, 0.22 m*M* KCl, and 11.42 m*M* NaCl) and applied to 6-well (10^5 cpm, 100 µg, 0.2 ml) tissue culture plates. Coated plates were dried under vacuum at room temperature for 3 days and used for the assay of plasminogen activator within 10 days.

The 6-well tissue culture dishes coated with ^{125}I-labeled fibrinogen were washed with Dulbecco's PBS to remove nonadherent material. At this stage each well contained 50,000–70,000 cpm, as determined by pronase digestion. Then, 5×10^4 tumorigenic or nontumorigenic cells were plated in 3 ml complete medium previously depleted of plasminogen by passage over lysine-Sepharose 4B (*20*). Soybean trypsin inhibitor (300 µg/ml) was added to inhibit any residual plasmin activity. Cells were incubated (37°C, 5% CO_2) overnight, the medium was removed, the cell layer was washed, and 1.5 ml RPMI-1640 medium containing 10% acid-treated NGPS was added. After a further 5-hour incubation, which permitted fibrin digestion, the medium was removed and counted for ^{125}I (cpm). Controls for spontaneous release due to cells alone (no NGPS), spontaneous release with no cells (medium plus NGPS), and total release (pronase, 80 µg) were included for each 6-well plate. The percentage of the total cpm released in each test well was calculated after correction for the activity in the two spontaneous release controls. The cell lines were assayed twice in triplicate, and the results were expressed as the mean of six determinations. NGPS was acid treated by titration to pH 3.0 with 1 *N* HCl, which inactivated acid-labile protease inhibitors, and was neutralized after 30 minutes with NaOH (*21*).

Assessment of anchorage-independent growth.—Cloning efficiency of tumorigenic cells in 0.35% agar in complete medium was assessed as described (*11*). Suspensions of 10^2 or 10^3 trypsinized cells in 5 ml complete medium containing 0.35% liquid agar at 40°C were prepared and immediately poured onto a 4-ml basal layer of 0.7% agar in complete medium in a 60-mm petri dish. The dishes were incubated (37°C, 5% CO_2) and examined by phase-contrast microscopy at 7, 14, and 21 days for the presence of colonies growing in the 0.35% agar. After 21 days the colonies were stained by the addition of 1 ml of a 1:100 dilution in medium of a 1:300 solution of neutral red/dish. Only colonies containing more than 100 cells were counted.

Fibronectin localization and quantitation.—Fibronectin was purified from normal guinea pig plasma by gelatin-Sepharose 4B affinity chromatography as described by Engvall and Ruoslahti (*22*). Xenoantisera were produced in New Zealand White rabbits, heat inactivated (56°C, 30 min), and absorbed with three volumes of SRBC and two volumes of guinea pig erythrocytes. Control sera obtained from the same rabbits before immunization were similarly absorbed. Analysis of the xenoantisera by double diffusion and immunoelectrophoresis against normal guinea pig plasma indicated specificity for fibronectin.

Immunofluorescence was evaluated in tumorigenic and nontumorigenic cells on Lab-Tek 8-chamber culture slides seeded with 2.5×10^4 cells in complete medium and incubated (37°C, 5% CO_2) until confluent. The slides were washed in PBS, fixed with 3.5% phosphate-buffered Formalin (60 min, 25°C), and rinsed with PBS. Xenoantisera or control sera (50 µl/chamber, 1:80 dilution) were added for 60 minutes, and the slides were rinsed and incubated with fluorescein isothiocyanate-conjugated goat anti-rabbit IgG (50 µl/chamber, 1:20 dilution) for another 60 minutes. The slides were washed, and fluorescence was determined with a Leitz Ortholux II equipped for fluorescence microscopy with Ploem illumination for fluorescein, as previously described (*23*). Photomicrographs were taken with Kodak Tri X-film (ASA 400). No fluorescence was seen with the control sera on any of the cells tested, and none of the absorbed sera when reacted with SRBC showed fluorescence.

Relative quantitation of the amount of fibronectin bound to the cells and incorporated into the extracellular matrix was obtained in a radiobinding assay in which the erythrocyte-absorbed xenoantisera and ^{125}I-labeled SpA were used. The procedure has been described in detail (*24*). Protein A was radiolabeled to a specific activity of 4×10[illegible] cpm/μg with Bolton-Hunter reagent (*25, 26*). Tumorigenic and nontumorigenic cells (5×10^4, 0.1 ml) in complete medium were seeded in 96-well flat-bottom tissue culture plates and incubated (37°C, 5% CO_2). The next day, the medium was removed by a quick shake of the inverted plate, the adherent cells were washed with 0.1% OA in PBS, and 50 μl of diluted xenoantisera (1:10–1:80 in OA–PBS) was added. After 60 minutes' incubation at room temperature, unbound antisera were removed by three washes with OA–PBS, 50 μl of ^{125}I-labeled SpA (20 ng) was added to the cells, and incubation was continued for 30 minutes at room temperature. Excess ^{125}I-labeled SpA was removed by washing the wells with OA–PBS, the cells were then digested with 1 *N* NaOH, and the digest was counted for ^{125}I (cpm). The results were expressed as the percentage of total cpm of ^{125}I (^{125}I-cpm) bound to the digested cells.

Lymphotoxin inhibition of cell growth.—Production of 2/N guinea pig lymphotoxin by peritoneal leukocytes and analysis of the activity were described in detail (*9*). Mineral oil-induced leukocytes were harvested, washed, and suspended in serum-free RPMI-1640 medium at 5×10^5 cells/ml (20 ml/100-mm dish). Phytohemagglutinin (100 μg/ml) was added immediately, and the guinea pig lymphotoxin-containing culture medium was collected after 24 hours and frozen at −40°C. Guinea pig lymphotoxin was assayed in a [^{3}H]dThd release assay with murine αL929 target cells. One U of lymphotoxin induced 50% release of [^{3}H]dThd from 10^4 target cells in 72 hours (*27*).

Measurement of target cell susceptibility to the colony inhibitory activity of guinea pig lymphotoxin has been previously described in detail (*15*). Single cell suspensions of target cells were obtained by mild trypsinization (0.1% trypsin) of exponentially growing cultures of tumorigenic and nontumorigenic cells. The cell suspensions were diluted with complete medium to contain 100–1,000 cells/4 ml to produce 30–60 colonies and were plated in 60-mm petri dishes. Guinea pig lymphotoxin was included in the complete medium at 6, 60, or 600 U/ml. Each assay was performed in sextuplicate. After 7 days of incubation (37°C, 5% CO_2), the medium was removed and the colonies were washed with PBS, fixed in methanol, and stained with 10% aqueous Giemsa. Colonies greater than 0.2 mm in diameter were counted. Target cell response to guinea pig lymphotoxin was expressed as a percentage of the number of colonies in the untreated control group. Less than 10% inhibition of colony formation was not considered significant. The reproducibility of this assay is ±5%.

Intradermal skin tests.—Exponentially growing tumorigenic and nontumorigenic cells were harvested from 100-mm culture dishes with 5 ml 1:5,000 EDTA and were washed twice with RPMI-1640 medium. The cells, resuspended at 2.5 or 5.0×10^7 cells/ml RPMI-1640 medium, were injected (0.1 ml) id into the shaved abdomen of healthy nonimmunized 14- to 16-week-old male 2/N guinea pigs. Each cell line was tested in 6 animals; each animal received four injections of different cell lines at separate sites 4 cm apart. Reactivity was determined by the calculation of the average diameter of induration of two perpendicular measurements 1, 2, 3, and 4 days after inoculation. Results were expressed as an index of reactivity, which was the ratio of the mean induration on day 4 to the mean induration on day 1 calculated by linear regression analysis of the indurations on days 1, 2, 3, and 4. Portions of these data were included as part of another report (*9*).

Determination of tumorigenic threshold dose.—Chemical carcinogen-treated neoplastic cells were assessed for their tumorigenic ability in adult guinea pigs. Exponentially growing cultures of cells were harvested by mild (0.1%) trypsinization, washed twice with RPMI-1640 medium, and resuspended in this medium at tenfold increments from 10^2 to 10^6 cells/ml. Groups of six 12- to 20-week-old 2/N guinea pigs received sc injections in the flank of 1.0 ml of each cell suspension. Each guinea pig received only cells of one cell line. Tumor growth was monitored for 6 months. The lowest number of cells producing a progressively growing tumor in at least half the group during this period was the minimum tumorigenic dose. Line 74C3 failed to produce a tumor in any guinea pig inoculated with 10^2–10^6 cells. However, within 2 months after injection of 10^7 cells, tumors appeared in 2 of 2 animals tested.

RESULTS

Five lines of in vitro transformed tumorigenic syngeneic 2/N guinea pig cells and four controls were studied for expression of selected phenotypic properties. Three of the four controls were nontumorigenic guinea pig cells representing *a*) long-term-cultured (culture 106) carcinogen-induced morphologically transformed nontumorigenic cells, *b*) intermediate-term-cultured (culture 103) cells treated with acetone (a noncarcinogen) and possessing a nontransformed morphology, and *c*) low-passage secondary culture (2°) untreated cells.

Tumorigenic cells were distinguishable from nontumorigenic cells by production of plasminogen activator. Plasminogen activator was produced by all tumorigenic cells in amounts that correlated with their tumorigenicity (table 2). Nontumorigenic cells were not active, as evidenced by their failure to release ^{125}I-cpm after plasminogen was added, even when the incubation time with plasminogen was extended to 24 hours and the cell number in each well was increased to 1×10^5. In a 48-hour assay with 2×10^5 cells, culture 103 had sufficient activity to digest 34% of the ^{125}I-labeled fibrin; culture 106 and the 2° culture cells produced no activity under these conditions (data not shown).

Activation of plasminogen by tumorigenic cells may be a factor in the expression of anchorage-independent growth and in the determination of the amount of fibronectin deposition in intercellular areas. To see whether a relationship exists among plasminogen activator production, anchorage-independent growth, fibronectin deposition, and tumorigenicity, we determined the cloning efficiency of guinea pig cells in medium containing 0.35% agar and the

TABLE 2.—*Properties of tumorigenic guinea pig fibroblast-like cells*

[d] No tumors were observed after injection of 10^8 cells.

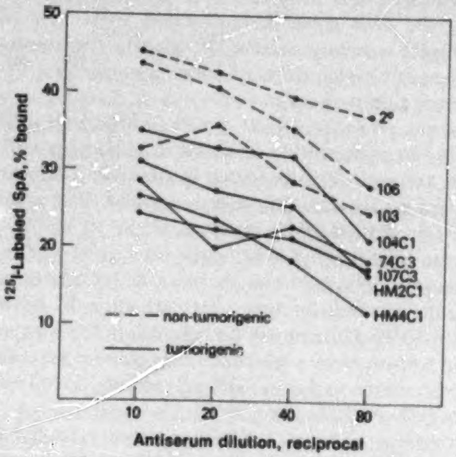
[e] Nontumorigenic cells were not sensitive to lymphotoxin-inhibited colony formation.

pattern and quantity of fibronectin incorporation into an extracellular matrix.

Only tumorigenic guinea pig cells formed colonies in soft agar. Efficiency of colony formation by tumorigenic cells ranged from 2.4 to 27.1%, but the ranking showed correlation neither with the amount of plasminogen activator produced by the cells nor with the minimum required tumorigenic dose (table 2). Lowest cloning efficiencies were seen with highly tumorigenic cells producing the most plasminogen activator (HM2C1 and 104C1), and highest efficiency was obtained with the weakly tumorigenic cells producing the least amount of plasminogen activator (line 74C3). The relationship was not strictly reversed since cells of line HM4C1 showed a higher cloning efficiency, higher plasminogen activator activity, and greater tumorigenicity than cells of line 107C3.

Fibronectin production and extracellular deposition by the guinea pig cells were studied by indirect immunofluorescence in which rabbit antisera to guinea pig plasma fibronectin were used. A distinctly different pattern of immunofluorescence was seen with the nontumorigenic cells as compared to the tumorigenic cells. Nontumorigenic 2° culture cells (fig. 1A) and culture 103 cells showed a pattern of extracellular matrix-associated fluorescence that outlined the cells and revealed their ordered arrangement. Carcinogen-treated morphologically transformed nontumorigenic culture 106 cells exhibited a fluorescence pattern similar to that seen with nontumorigenic culture 103 and 2° cells, revealing an extracellular matrix of fibronectin that outlined the cells, illuminating their random pattern of growth (fig. 1B). In contrast, tumorigenic cells showed a surface rather than an extracellular matrix-associated fluorescence of weak intensity and patchy appearance (fig. 1C). Tumorigenic cells could not be distinguished from each other by their pattern of immunofluorescence. A rabbit antiserum to human plasma fibronectin was used with similar results.

We determined the relative amount of cell-bound and extracellular fibronectin produced by each cell line in a radiobinding assay with rabbit anti-guinea pig fibronectin antisera and ^{125}I-labeled SpA to learn whether differences between tumorigenic and nontumorigenic cells could be quantitated. Nontumorigenic cells, after incubation with antisera to fibronectin, bound more ^{125}I-labeled SpA and thus produced more fibronectin than did tumorigenic cells, but in all assays no clear distinction between tumorigenic and nontumorigenic cells was possible on the basis of the quantity of fibronectin produced (text-fig. 1; table 2). The binding data were confirmed in three similar experiments, with the only differences attributed to decay of the radiolabel.



TEXT-FIGURE 1.—^{125}I-labeled SpA quantitation of anti-guinea pig fibronectin xenoantisera bound to tumorigenic and nontumorigenic guinea pig cells. Diluted xenoantisera (50 µl) were reacted with 5×10^4 cells per line per 96-well tissue culture plate. After removal of unbound xenoantibody, bound antibody was reacted with 20 ng (10^5 cpm) ^{125}I-labeled SpA. *Each point* is the mean of duplicate determinations. In the absence of antisera, the amount of bound ^{125}I-labeled SpA ranged from 1.1 to 1.4%.

Tumorigenicity, plasminogen activator synthesis, soft agar cloning efficiency, and fibronectin production by tumorigenic guinea pig cell lines were also compared. No correlation of fibronectin production with any of the other properties of the cells was revealed (table 2).

Since tumorigenic cells are sensitive to the colony-inhibitory activity of homologous lymphotoxin and nontumorigenic cells are not sensitive, we were interested in determining whether this sensitivity correlates with any of the other phenotypic properties. Lymphotoxin inhibited colony formation by tumorigenic cells but had no inhibitory effect on nontumorigenic cells. In the colony formation assay the tumorigenic but not the nontumorigenic cells were inhibited as much as 85% by 600 U lymphotoxin. Lymphotoxin sensitivity showed a direct correlation both with the amount of plasminogen activator produced and with the tumorigenicity of the cells (table 2): The most highly tumorigenic cells produced the most plasminogen activator and were most sensitive to lymphotoxin (line HM2C1), the least tumorigenic cells produced the least amount of plasminogen activator and were least sensitive to lymphotoxin (lines 743C3 and 107C3), and the other two cell lines were intermediate in tumorigenicity and ranked in the same order of plasminogen activator production and lymphotoxin sensitivity. Lymphotoxin sensitivity did not correlate with soft agar cloning efficiency or fibronectin production.

Within 24 hours after id injection of 2–5$\times 10^6$ cells into syngeneic nonimmune guinea pigs, an area of induration up to 5-mm diameter appears (*9*). When nontumorigenic cells are injected, the response rapidly subsides, but with tumorigenic cells the response increases, persists, or subsides slowly over 4 days at a rate characteristic of the cell line (*9*). Expression of this natural delayed-type skin reactivity by tumorigenic guinea pig cells correlated with the tumorigenic ability of the cells, the production of plasminogen activator, and sensitivity to lymphotoxin. No correlation was seen with soft agar cloning efficiency or fibronectin production (table 2).

DISCUSSION

Three properties of tumorigenic guinea pig cells—plasminogen activator production, lymphotoxin sensitivity, and the capacity to elicit a tuberculin-like delayed id skin response in nonimmune syngeneic guinea pigs—correlated quantitatively with the capacity of the cells to produce a progressively growing tumor in syngeneic animals. Two properties—cloning efficiency in 0.35% agar and the pattern of extracellular fibronectin deposition—distinguished the tumorigenic and nontumorigenic cells, but the quantitative expression of these properties did not correlate with the degree of tumorigenicity. This finding is in accord with results from other laboratories indicating a frequent but not a necessary correlation among the properties of anchorage-independent growth, decreased fibronectin incorporation, and tumorigenic ability (*28–30*). Our findings with regard to fibronectin may have been influenced by the period of in vitro culture. Yamada et al. (*31*) and Chen et al. (*32*) reported decreased fibronectin production by cells after, respectively, establishment of a permanent cell line and extensive passage in culture. The possibility that the amount of fibronectin detected in our experiments was related to those factors was not excluded, and among fresh cell isolates, a clear quantitative distinction among cells of differing tumorigenic abilities may be observed. It is also possible that further experiments will show, as suggested by current data, that the change in fibronectin production with transformation covers a continuous spectrum, with no clear distinction among tumorigenic cells or between groups of nontumorigenic and tumorigenic cells.

That tumorigenic cells produced plasminogen activator in amounts which correlated directly with their tumorigenic ability and that nontumorigenic cells produced no activator in the same assay suggest a functional relationship between in vivo growth of tumor cells and plasminogen activator. In vivo evidence implicating plasminogen activator and tumor development also includes the identification of plasminogen activator in extracts of established tumors (*33–35*) and in histologic tumor tissue sections (*2*) and the demonstration of relatively greater plasminogen activator concentrations in metastatic as compared to primary tumor tissue (*36*). Dvorak et al. (*37, 38*) suggested a mechanism whereby plasminogen activator may promote tumor formation. They reported that a principal difference between spontaneously regressing (line 1) and highly malignant (line 10) guinea pig tumors was the amount of fibrin gel surrounding the growing tumors. Line 1 tumors were encapsulated by fibrin to a greater extent than line 10 tumors; Dvorak et al. postulated that plasminogen activator promoted fibrin digestion which permitted tumor growth and possibly stimulated growth of blood vessels into the developing tumor mass. Extensive fibrin deposition during tumor growth has also been observed by other workers (*39, 40*), and our studies of the histology of the induration produced by id injected tumorigenic guinea pig cells indicate that within 4 days a well-ordered fibroblast-rich matrix begins to develop around the nascent tumor cells (McCabe RP, Oneson R, Evans CH: Unpublished data). In the light of these observations, we may reasonably suggest that in some instances plasminogen activator can influence tumor development by limiting the isolation of the tumor within a fibrin matrix and by promoting angiogenesis.

Our laboratory (*9*) described the sensitivity of tumorigenic guinea pig fibroblasts to the colony inhibitory activity of homologous lymphotoxin and the capacity of these fibroblasts to induce natural delayed tuberculin-like skin reactivity in nonimmune animals. These properties of tumorigenic fibroblasts were shown to develop during the course of carcinogenesis at approximately the same time as the cells became tumorigenic. In the present work we show that these two properties correlate quantitatively with tumorigenicity, as measured by the minimum tumorigenic dose, and that their expression is related to a third factor, plasminogen activator. Zwilling et al. (*10*) demonstrated that the susceptibility of these guinea pig fibroblasts to lymphoid cell natural cytotoxic activity also correlated with tumorigenicity. That study showed a continuum in natural leukocyte cytotoxicity, as observed for natural delayed skin reactivity in the present investigation. Together, these responses indicate the differential capacity on the part of the recipient or host animal to recognize and respond to nascent tumorigenic cells and the differential susceptibility of these cells to possible defense mechanisms. The correlation with plasminogen activator activity does not provide a clear picture; yet these findings, together with the known importance of protease activities in cell functions (*41–44*), the inhibitory effect of protease inhibitors on lymphotoxin activity (*45*), and the mitogenic activity of some proteases for lymphocytes (*46*), indicate the need for further investigation into the relationships of these activities to each other. Since cells most sensitive to effectors of natural immunity also produce the greatest amount of plasminogen activator, a mechanism may exist whereby immunologic effector cells or soluble factors mediate their activity through the action of target cell proteases.

Meeting Highlights

Kaposi's Sarcoma in Homosexual Men

On September 15, 1981, a meeting was convened at the National Cancer Institute (NCI), Bethesda, Maryland, to discuss an apparent epidemic of Kaposi's sarcoma in homosexual men living in New York and California over the past 2 years. This conference was sponsored jointly by the Division of Cancer Treatment, NCI, and the Communicable Disease Centers (CDC), Atlanta, Georgia.

Kaposi's sarcoma was first described in 1872 as a rare, multicentric, pigmented sarcoma of uncertain histogenesis, commonly found among older men of Jewish, Italian, or Eastern European origin. It was later discovered to be endemic in parts of tropical Africa. More recently, a large excess of Kaposi's sarcoma was noted among renal allograft recipients and other immunosuppressed patients. Since 1979, the CDC reported over 70 cases of Kaposi's sarcoma among homosexual males, many of whom are profoundly immunodeficient and are afflicted with opportunistic infections such as *Pneumocystis carinii* pneumonia. The NCI–CDC meeting focused on the "state of the art" of clinical features, epidemiology, etiology, and treatment of Kaposi's sarcoma.

Histologically, the tumor consists of spindle cells, some containing vascular "slits," with an admixture of lymphocytes. Monomorphic or anaplastic patterns are also described; the anaplastic pattern correlates with more aggressive clinical lesions. Kaposi's sarcoma in endemic areas of Africa follows several clinical patterns: a lymphadenopathic type, common in childhood; a nodular type, characteristically subcutaneous and indolent; a "florid" or sarcomatous type, showing aggressive local behavior; and an infiltrative, deeply invasive type. In nonendemic areas, Kaposi's sarcoma first appears as bluish cutaneous nodules, patches, or plaques.

The varied clinical appearance and course of Kaposi's sarcoma do not adapt well to classical staging systems. At the NCI meeting, a staging scheme was adopted that encompasses all cases, whether endemic, nonendemic, or epidemic. Anatomic distribution defines two categories: local–regional or generalized. Clinical behavior in each category may be "indolent" or "aggressive," features that reflect disease tempo and progression.

The consensus as to treatment was that local–regional cases should be treated with radiotherapy, while patients with generalized disease require chemotherapy with the use of single agents (e.g., Velban or a trial of VP-16 vs. ICRF-187) for indolent tumors or combination chemotherapy for aggressive tumors. Because of the favorable chemosensitivity of this tumor, two non-cross-resistant regimens were selected: dactinomycin, dacarbazine, and vincristine, alternating every 3 weeks with doxorubicin, Velban, and bleomycin.

Data associating Kaposi's sarcoma with cytomegalovirus (CMV) were reviewed. Five of 8 tissue cultures of African biopsy specimens disclosed a CMV-like virus on electron microscopy. Compared to controls, African patients do not show elevation of CMV antibody titers, but control levels are high anyway, possibly obscuring a difference. Seroepidemiology in European patients, however, revealed a strong association with CMV antibody elevation. Studies of allograft recipients receiving immunosuppressive therapy and of homosexual males with Kaposi's sarcoma also reveal high antibody titers to CMV. The most compelling link was the detection of the CMV-related antigen in 7 of 31 African tumor biopsy specimens and in 4 of 12 tumor cell lines and CMV–DNA homology in 3 of 8 tumor biopsy specimens. Since CMV has oncogenic potential in vitro, its association with human neoplasia, both in endemic and epidemic cases, needs more study.

Epidemiologic data disclose two recent patterns associated with the risk of Kaposi's sarcoma. One is an acquired immunodeficiency syndrome, characterized by multiple opportunistic infections, anergy, and in extreme cases, a "wasting" syndrome. *Pneumocystis carinii* is a particularly prominent pathogen, reported in 54 homosexual men over a 4-year period. Fourteen additional patients with *Pneumocystis carinii* pneumonia also had Kaposi's sarcoma. The pathogenesis of this apparently sex-linked immunodeficiency syndrome is not known. Postulated mechanisms include CMV infection (perhaps a strain that is tropic for T-lymphocytes) or adverse effects of inhaled or ingested drugs on the immune system.

The second risk feature is the use of nitrite inhalants among homosexual men. Up to 88% of Kaposi's sarcoma patients report regular use of isobutyl or amyl nitrite inhalants; the frequency of use parallels the number of sex partners. Possibly, the excessive use of nitrites in recent years accounts for the epidemic of Kaposi's sarcoma: Inhaled nitrites could combine with secondary amines to form highly carcinogenic nitrosamines that act on capillary endothelium to produce mutations and neoplastic transformation. In the setting of profound immunodeficiency, neoplasia would proceed unchecked by normal immunosurveillance mechanisms. It is further possible that the inhaled nitrites are in some way directly toxic to pulmonary macrophages, increasing local susceptibility to opportunistic pulmonary infection.

The workshop concluded with a number of recommendations. First, the coordination of investigations was essential and should be centralized by NCI. Representatives from the major epidemic areas, New York and California, agreed to collaborate on the epidemiology (through the CDC) and treatment programs (through the cooperative groups). Communications and procedures were established to study virologic and serologic aspects of Kaposi's sarcoma patients and controls. Various clinical and laboratory immunologic studies were proposed. Dr. William DeWys, Chief, Clinical Investigations Branch, Cancer Therapy Evaluation Program, Division of Cancer Treatment, NCI, agreed to coordinate the NCI activities, and Dr. James Curran, CDC, will manage the epidemiologic aspects. The epidemic of Kaposi's sarcoma in homosexual men is an "accident of nature" that requires prompt clinical attention to the victims and affords a unique opportunity to study a rare tumor.

Monoclonal Antibodies and Breast Cancer

The Diagnosis Working Group of the Breast Cancer Task Force, National Cancer Institute (NCI), sponsored a workshop on the use of monoclonal antibodies in breast cancer on June 29, 1981, in Bethesda, Maryland. The purpose of the workshop was to determine whether monoclonal antibodies are available that can assist physicians in establishing a diagnosis of breast cancer or in estimating prognosis. We were also interested in learning about the major advances and in determining which areas needed further stimulation. The workshop proved especially informative since most of the work presented had not been published. In addition, the workshop helped to foster communication between investigators making monoclonal antibodies and pathologists who would ultimately use them.

Investigators have used a variety of approaches for producing monoclonal antibodies that react with malignant or normal breast tissue. One approach was to use antigens known to be present on breast cancer cells, such as estrogen receptor(s) (ER) (G. Greene, University of Chicago, Chicago, Ill.) or histocompatibility antigens (S. Ferrone, Scripps Clinic and Research Foundation, La Jolla, Calif.). Another approach has been to use whole cells or the membrane fractions as antigens. One group used membrane fractions from liver metastases (J. Schlom, NCI), while others (Z. Steplewski, The Wistar Institute, Philadelphia, Pa.; D. Yuan and F. Hendler, University of Texas Southwestern Medical School, Dallas, Tex.; K. Grzyb, University of Texas Health Science Center at San Antonio, San Antonio, Tex.) preferred cell lines because of their accessibility and reproducibility. One problem, however, associated with the use of cell lines is the loss of some antigens during prolonged passage (Schlom; R. Ceriani, Children's Hospital Medical Center, Oakland, Calif.). For example, one of Schlom's monoclonal antibodies reacts with MCF-7 cells, but only up to passage 319, while another monoclonal antibody no longer reacts with MCF-7 after passage 317. A third approach taken by J. Hilgers (The Netherlands Cancer Institute, Amsterdam, The Netherlands) and Ceriani was to use milk fat globules as the immunogen. These milk fat globule antigens are produced by cells that have reached the most highly differentiated state and therefore may be useful markers for differentiation.

The importance of using multiple assays to screen and characterize monoclonal antibodies was emphasized by J. D. Minna (NCI–Veterans Administration Medical Oncology Branch, Washington, D.C.). Since several thousand hybridoma supernatants must be screened to obtain only a few interesting monoclonal antibodies, the initial screening assay should test several hundred supernatants rapidly and reproducibly. Most investigators preferred a solid-phase assay in which the binding of monoclonal antibody to antigen was detected by either an enzyme-linked second antibody or iodinated protein A.

In addition to screening monoclonal antibodies for binding to cells, several investigators tested monoclonal antibodies for other properties. For instance, some monoclonal antibodies were screened by Schlom for antibody-dependent cellular cytotoxicity to determine which antibodies may be useful for immunotherapy. Ferrone uses only monoclonal antibodies that identify antigens by immunoprecipitation so that there is no question about the antigen under study. Minna is measuring antibody against tumor-associated antigens in human sera by inhibition of the binding of monoclonal antibody. The assay can detect as little as 7–10 ng of antibody.

Of greatest interest to pathologists were the patterns of reactivity on tissue sections. These were revealed by several common immunohistochemical methods—fluorescence, peroxidase, or avidin–biotin-coupled systems. Yuan and Hendler have developed an assay utilizing iodinated monoclonal antibodies to measure their binding to tissue sections. By this method over a hundred tissue sections can be assayed overnight, and several observers can assess the results simultaneously.

As one would expect, the method of fixation is very important for the binding of monoclonal antibodies to tissue sections. Only some antigens recognized by monoclonal antibodies survive Formalin fixation, which is unfortunate since it will limit retrospective studies with stored Formalin-fixed tissues. B-5, a mercuric chloride Formalin fixative (R. Cardiff, University of California at Davis, Davis, Calif.), ethanol on frozen sections (L. Pertschuk, Downstate Medical Center, Brooklyn, N.Y.), and B-5 plus Bouin's fixative (M. Nadji, University of Miami, Miami, Fla.) were all superior to Formalin. Zenker's and Bouin's fixatives tended to displace the antigens into the cytoplasm, even those that were located along the cell surface in frozen sections. Because of the vagaries of fixation, it may be advisable to use frozen tissue for immunocytochemical staining.

None of the investigators were able to produce a monoclonal antibody that reacted exclusively with breast cancer. The patterns of cross-reactivity with normal tissues and other tumors varied with each monoclonal antibody and were unpredictable. Some monoclonal antibodies obtained by Schlom reacted with a majority of malignant breast tumors, whereas others reacted with only certain cells of some cancers other than breast cancers. None of the monoclonal antibodies tested reacted with the cell surface of melanomas or sarcomas, which is not unexpected in view of the epithelial origin of breast carcinomas. Many monoclonal antibodies, however, reacted with various carcinoma cell lines, especially those derived from the colon. Whether this indicates broad antigenic overlap between colon and breast carcinomas remains to be determined. Some monoclonal antibodies reacted with the cytoplasm or secreted proteins of certain breast biopsy specimens as detected by immunoperoxidase staining.

One monoclonal antibody also stained sweat glands, which is not surprising in view of the embryologic origin of the mammary glands. Perhaps this monoclonal antibody will be useful in the diagnosis of sweat gland tumors. Some monoclonal antibodies that reacted against breast cancer tissue also reacted with the normal epithelium adjacent to the tumor. Schlom suggested that this could be the result of adsorption of shed tumor antigens, preneoplastic changes in adjacent epithelium, or production of some factor by the tumor that stimulated the normal tissue to express this antigen. Cardiff mentioned that because of the sensitivity of tissue sections, one positive cell in 10^6 could be detected. Thus a monoclonal antibody that appeared to be very specific by routine binding assays could show a much wider reactivity on tissue sections. Hilgers reminded the audience that one of the first differentiation antigens to be discovered, i.e., theta for thymocytes, is also present in brain tissue. Furthermore, this antigen can be detected in the stroma of mammary and colon tissues.

It will be very surprising if antigens are discovered that are present on only cancerous breast tissue. More likely, what will be found are antigens present on several tissues, but there will be quantitative differences in the expression of these antigens. The monoclonal antibodies will appear to be more specific the less sensitive the assay system. It is also possible that some monoclonal antibodies that bind to both benign and malignant breast tumors may indicate a better prognosis, since this overlap may mean that a high proportion of differentiated cells is present in the malignant tumors (Yuan and Hendler).

It was suggested that some of the cross-reactions seen with other tumor tissues may indicate a common cell within the tumors. For instance, Minna reported a monoclonal antibody that reacted with small cell carcinoma of the lung in addition to breast carcinoma, and Schlom found that many of his monoclonal antibodies against breast cancer also reacted with colon cancer. This phenomenon is possible if a common cell, such as an uncommitted stem cell, is present in many tumors.

Heterogeneous reactivity of tumor cells has been previously observed with xenogeneic antisera, but there was always some doubt that this represented true heterogeneity, because of the possible polyspecificity of the xenoantibodies. This heterogeneity has now been firmly established by monoclonal antibodies. In fact, this may be an important contribution of monoclonal antibodies to our understanding the nature of neoplasia. This heterogeneity was observed in different ways. For example, monoclonal antibodies may react with only some cells in the primary tumor or not with all metastatic foci in lymph nodes (Cardiff and Ceriani). There is heterogeneity in cell lines as well, even after cloning (Ceriani). Some variations in staining may not be the result of true heterogeneity, but rather the differential expression of antigens during the cell cycle or loss of antigens after many mitoses. Tumor cell lines are heterogeneous with respect to both stain intensity and size after analysis in the fluorescence-activated cell sorter (Schlom and collaborators; Yuan and Hendler).

Some of the antigens reacting with monoclonal antibodies have been characterized by immune precipitation and sodium dodecyl sulfate polyacrylamide gel electrophoresis (Schlom, Ferrone, and Hilgers). These antigens range from 30,000 to over 200,000 daltons. Yuan and Hendler identified an antigen on two-dimensional gel electrophoresis that was composed of two chains of 30,000 daltons, each chain with a different pI. Clearly, monoclonal antibodies will be valuable tools for the purification and characterization of tumor-associated antigens.

Ferrone studied the expression of the human histocompatibility antigens (HLA-A, HLA-B, HLA-C, and HLA-DR) on breast tumor cells. It has been shown in other systems that cells undergoing malignant transformation exhibit quantitative and sometimes qualitative changes in the expression of these antigens. In addition, evidence indicates that there may be an association of histocompatibility antigens with some tumor antigens.

The following patterns were seen with breast cancer cell lines. The monoclonal antibody against HLA-A, HLA-B, and HLA-C heavy chain was positive with all cell lines tested, but there were quantitative differences among the cell lines. There was an excess of β_2-microglobulin compared to the HLA heavy chain on some breast tumors, especially on infiltrating ductal carcinomas, lobular carcinomas, and tubular carcinomas, but not on medullary carcinomas. The Ia-like monoclonal antibody that reacts with melanoma cells was negative on three breast cell lines and weakly positive on two cell lines. The monoclonal antibody directed against the 85,000-dalton component that is present on melanomas and lymphocytes was present on all breast cell lines, but the degree of reactivity varied widely. The 94,000 component that is present on melanomas and absent on lymphocytes was present on only some breast cell lines, and the amount of antigen present varied with each cell line. The high-molecular-weight antigen that is found on melanomas was absent on lymphocytes and all breast cell lines tested.

M. Unger (The Salk Institute, La Jolla, Calif.) has obtained several monoclonal antibodies against rat mammary differentiation antigens. Two of these also reacted with normal rat ovary. These monoclonal antibodies may be useful for the study of normal differentiation antigens in other tissues in addition to the mammary gland.

Monoclonal antibodies prepared against ER can provide a more sensitive and reproducible assay for evaluating the ER status of breast cancer (Greene). The assay consists of a monoclonal antibody directed against one epitope on the receptor as a bridge between a plastic surface and the receptor and a second, radiolabeled monoclonal antibody against a different epitope to measure the amount of ER bound and thus the amount of receptor present in the cytosol. The assay, which is as sensitive as current biochemical methods, is simpler to perform and does not require labeled estrogen.

Pertschuk and Nadji are using these monoclonal antibodies to localize ER with either fluorescence or peroxidase staining. The method of tissue fixation is very important for preservation of the reaction of the monoclonal antibody with the hormone receptors. Slow dehydration in ethanol appears to be optimal in Pertschuk's laboratory. Heterogeneity of staining is commonly observed, as mentioned by previous speakers. In fact, fixation adds another variable over and above the heterogeneity. In a retrospective study, 23 tumors were ER-positive by immunohistochemical and biochemical measurements, 20 were negative by both methods, 6 were negative by fluorescence but positive by biochemical methods, and 4 were the reverse. In a prospective study, 28 were positive by both methods, 2 negative by both methods, 5 negative by fluorescence and positive by biochemical methods, and none the reverse.

Our ability to assess the ER status directly on tissues will become more important as smaller tumors are detected and sample size is limited. We should also be able to assess the ER status of needle aspirates, bone biopsy specimens, and pleural effusions. The proportion of normal or necrotic tissue to the tumor mass can be visualized directly in histological sections, which is an advantage, especially when ER concentration is measured on a unit per weight basis in cytosols. Yuan and Hendler have an interesting monoclonal antibody that binds only to cells that have a cytoplasmic ER, but the monoclonal antibody is directed against a cell surface component.

S. Halter (Vanderbilt University, Nashville, Tenn.) described a retrospective study of stage II mammary carcinomas evaluated for the association of either carcinoembryonic antigen or pregnancy-specific β_1-glycoprotein with survival. Since there was no correlation with survival, she concluded that monoclonal antibodies directed against other oncofetal antigens may be more useful for assessing prognosis.

W. L. McGuire (University of Texas Health Science Center at San Antonio) led the general discussion on the usefulness of monoclonal antibodies for detection and treatment of breast cancer. One concern expressed by all discussants was the heterogeneity of breast cancer cells, which seems to preempt the use of a single monoclonal antibody for diagnostic or therapeutic purposes. There was agreement that a mixture, or a cocktail, of monoclonal antibodies directed against many antigens will be necessary for treatment. It was also noted that some cytotoxic monoclonal antibodies will kill tumors if these antibodies are injected as late as 6 days after tumor implantation in mice.

However, in vivo killing has not been observed with ricin-conjugated antibody, presumably because of dissociation, although cells are killed in vitro by the complex. Chemical modification of the ricin A- and B-chains is being tried as a means to stabilize the conjugate in vivo. It was also suggested that a monoclonal antibody be used to isolate the antigen of interest and that the isolated antigen be used to produce xenoantisera against all epitopes on the antigen.

Results with the use of the monoclonal antibodies for imaging have been disappointing, but several groups are working to improve the technology, especially in the search for an isotope that is better than iodine-131.

P. E. Fast (The Upjohn Co., Kalamazoo, Mich.) and H. Battifora (City of Hope National Medical Center, Duarte, Calif.) summarized the workshop. Both believed that the available monoclonal antibodies will improve our understanding of the biology of breast cancer. Some will even prove useful for identifying breast cancer cells and for estimating prognosis. More research is needed to determine whether any of the monoclonal antibodies can detect an antigen present in serum that would be diagnostically useful. Frozen tissue banks may be necessary for retrospective studies, since many monoclonal antibodies do not react on Formalin-fixed tissues.

The general status of the field was best summarized by Hilgers who stated that we are now in an optimistic period. However, there are many details that must be worked out. It will take some time to sort out the data before we reach a more realistic period, when monoclonal antibodies can be applied to practical problems.

A feeling of optimism pervaded the workshop. All seemed to recognize that monoclonal antibodies have given us a new Kismet but that heterogeneity was swift to inflict retribution.

Announcements

The Journal *will publish notices of major meetings dealing with cancer. Submission of notices 6 months in advance is requested to permit timely publication.*

National Toxicology Program Conference

The National Toxicology Program of the U.S. Department of Health and Human Services will sponsor this conference entitled "Photobiologic, Toxicologic, Pharmacologic, and Therapeutic Aspects of Psoralens" to be held at the National Institutes of Environmental Health Science, Research Triangle Park, North Carolina, on March 1–3, 1982. The meeting will cover the basic and clinical aspects of psoralen photochemotherapy with special emphasis on psoralen photochemistry, interactions of psoralens with DNA, RNA, and proteins, acute and chronic toxicity, mutagenicity, carcinogenicity, structure and photosensitivity activity relationship, and clinical responses of various psoralens in relationship to photochemotherapy of psoriasis and vitiligo.

For additional information please contact Dr. Madhu A. Pathak at the Department of Dermatology, Harvard Medical School, Massachusetts General Hospital, Boston, Massachusetts 02114 (telephone: 617-726-3996) or Dr. June K. Dunnick at the National Toxicology Program, NIEHS, Research Triangle Park, North Carolina 27709 (telephone: 919-541-4811).

Latest NCI Monographs Published

Monograph No. 56: *Sarcomas of Soft Tissue and Bone in Childhood*: Topics presented and discussed during this Symposium included recent developments in diagnosis and treatment of rhabdomyosarcomas and Ewing's sarcoma, based on Intergroup studies and those at other medical centers here and abroad. Various aspects were covered: evaluation, epidemiology, pathology, psychological support of patients, surgical treatment, immunotherapy, and multimodal therapy. GPO Stock No.: 017-042-00150-1. Price: $14.00 in the United States, Canada, and Mexico; $17.50 elsewhere (includes mailing charges).

Monograph No. 57: *Surveillance, Epidemiology, and End Results Program: Incidence and Mortality Data: 1973–1977.* This volume provides detailed tabular information on the incidence of and mortality from cancer in 11 representative areas of the United States during the initial 5 years of the SEER Program. Data are classified according to the sex, race, age, and residence of the patient; anatomic site; and histologic type of cancer. An introduction explains the goals and operation of the SEER Program as well as the organization and presentation of the data. Tables for each SEER area are also introduced by the persons responsible for reporting the data. GPO Stock No.: 017-042-00156-1. Price: $23.00 in the United States, Canada, or Mexico; $28.75 elsewhere (includes mailing charges).

NOTE: Errata on pages 982–983, Appendix Table I, have been brought to our attention: Numbers of deaths are double the correct numbers. The rates are correct as given.

Other Monographs Available

No. 41: A limited number of the Third National Cancer Survey: Incidence Data were located and can now be ordered from the Government Printing Office. GPO Stock No.: 017-042-00180-1; price $11.50 ($14.40)*

No. 49: Workshop on Genitourinary Cancer Immunology; GPO Stock No. 017-042-00133-1; price $11.85 ($15.80)

No. 50: International Conference on Ultraviolet Carcinogenesis (soft cover only); GPO Stock No. 017-042-00149-8; price $7.70 ($9.60)

No. 51: Perinatal Carcinogenesis (soft cover only); GPO Stock No. 017-042-00146-3; price $7.70 ($9.60)

No. 52: Aspects of Cancer Research 1971–1978: Editorials from the Journal of the National Cancer Institute; GPO Stock No. 017-042-00140-4; price $14.30 ($17.90)

No. 53: Second Symposium on Epidemiology and Cancer Registries in the Pacific Basin; GPO Stock No. 017-042-00142-1; price $8.25 ($10.30)

No. 54: The Occurrence of Tumors in Domestic Animals; GPO Stock No. 017-042-00145-5; price $9.35 ($11.70)

No. 55: Experimental Evaluation of Antitumor Drugs in the USA and USSR and Clinical Correlations; GPO Stock No. 017-042-00144-7; price $12.10 ($15.10)

Send orders to Superintendent of Documents, U.S. Government Printing Office, Washington, D.C. 20402. Be sure to include title and stock number of volume desired. Payment is required in advance; make check or money order (foreign or domestic) payable to Superintendent of Documents. Please **DO NOT SEND** orders to the Editorial Office or the National Cancer Institute.

*Prices *in parentheses* are for countries other than the United States, Canada, or Mexico.

Journal of the National Cancer Institute

March 1982
Volume 68
Number 3

THE JOURNAL of the National Cancer Institute solicits manuscripts on original observations in laboratory and clinical research from all scientists. A manuscript is considered for publication with the understanding that it has not been published previously and is submitted exclusively to the Journal. Opinions expressed by the authors are not necessarily those of the publisher or its editors.

THE JOURNAL is published monthly (two volumes a year). The Secretary of Health and Human Services has determined that the publication of this periodical is necessary in the transaction of the public business required by law of this Department.

A MONOGRAPH SERIES covering proceedings of scientific meetings pertaining to cancer is also published. These books may be purchased from the Superintendent of Documents. Series subscriptions are not available and monographs are not included in a subscription to the Journal.

THE JOURNAL is for sale by the Superintendent of Documents, U.S. Government Printing Office, Washington, D.C. 20402. Price per copy, $6.00. Subscription price for two volumes per year in the United States, $65.00; foreign, $81.25. Payment is required in advance, and check or money order should be made payable to the Superintendent of Documents.

All inquiries regarding purchase of subscriptions or depository library distribution, including inquiries about missing issues and change of address, should be addressed to the Government Printing Office. The Government Printing Office requires payment in advance on all orders. Inquiries regarding missing issues or change of address for official subscriptions should be addressed to the Editorial Office, Room 850, Westwood Building, 5333 Westbard Avenue, Bethesda, Md. 20016.

Instructions to Authors

Text: Send one original and two copies. **Text-figures** (graphs, charts, and line drawings): Send one original and two copies. **Figures** (photomicrographs and photographs): Send three original glossy prints, unmounted. **Tables:** Send tabular material in typewritten form; do not submit tables as glossy prints to be photographed. The entire manuscript including footnotes, legends, and references must be typed double spaced. Single-spaced portions of a manuscript will be returned to the author for retyping. The mailing address is: Journal of the National Cancer Institute, Westwood Building, Room 850, 5333 Westbard Avenue, Bethesda, Maryland 20016.

Manuscripts should be accompanied by a covering letter from the author responsible for correspondence about the manuscript. The covering letter should contain a statement that the manuscript has been seen and approved by all authors and that all persons listed as authors have made significant (not merely administrative, technical, or supervisory) contributions to the content of the paper. The letter should also state that the manuscript or substantial portions thereof have not been previously published nor are they under consideration for publication in another journal.

Data too extensive for inclusion in a manuscript, but which may be of interest to other investigators, may be deposited with the National Auxiliary Publications Service (NAPS), c/o Microfiche Publications, P.O. Box 3513, Grand Central Station, New York, New York 10017. Authors using the NAFS facilities should indicate in a footnote how their additional data may be obtained.

TITLE: Be brief (no more than 14 words, if possible), but for indexing purposes include all key words. The annual subject index is prepared directly from the titles. Titles that form complete sentences are not acceptable. Do not use abbreviations or chemical formulas in titles.

BYLINE: Supply the complete first name, middle initial, and last name of each author. Avoid use of nicknames. Academic degree is optional; however, if a degree is provided for one author, it should be provided for all authors on a manuscript. Include the name of the institution, address, and zip code for each author. Indicate address for reprint requests in a footnote on the byline.

ACKNOWLEDGMENTS: Financial aid in support of research should be recognized in a footnote. Aid in technical fields, animal care, photography, stenography, and other areas may be mentioned in a separate footnote. Indicate the title (Dr., Mr., Mrs., Miss, Ms.) and affiliation of each person acknowledged.

ABSTRACT: Provide an abstract, 150 words or less, on a separate page. The abstract should describe only *results* of the work being reported. Speculation, historical background, or reference to published works will be deleted from abstracts. Any inbred strains, noninbred stocks, cell lines, or other living materials used in the work should be noted in the abstract.

TEXT: Avoid the use of laboratory jargon and abbreviations not in common usage. When possible, refrain from the use of abbreviations that form words (exceptions are PAGE, ALL). Whenever possible, write mathematical equations and chemical formulas on a single line; submit complicated chemical structures as artwork. Avoid repetition of data in the text when it is presented in tables or text-figures.

Use the following style sources: Webster's *Third New International Dictionary* and Dorland's *Illustrated Medical Dictionary* (25th ed) for spelling; *Council of Biology Editors Style Manual* (4th ed) for scientific abbreviations and symbols: *Government Printing Office Style Manual* for other abbreviations and symbols, punctuation, and hyphenation; *Biochemical Nomenclature and Related Documents* (IUB, 1978) for abbreviations of chemical substances; *Enzyme Nomenclature*, recommendations (1978) of the IUB for recommended names of enzymes and information on nomenclature of isozymes; *The Merck Index* (9th ed) for chemical compounds; "Standard Nomenclature for Inbred Strains of Mice: Seventh Listing" by Joan Staats (Cancer Res 1980;40: 2083-2128) for inbred mouse strains; "Standardized Nomenclature for Inbred Strains of Rats: Fourth Listing" by Joan Staats and Michael Festing (Transplantation 1973;16:221-245) for designations of inbred rat strains; *Animals for Research* (9th ed) prepared by the Institute of Laboratory Animal Resources, National Academy of Sciences, for designations of laboratory animal stocks and strains.

TABLES: Submit tabular material typed double spaced on a separate page. Computer print-outs of tables are acceptable only if they are double spaced and with satisfactory title, column headings, legends and other textual material. Provide headings for all columns of a table and indicate units of measurement where applicable.

TEXT-FIGURES: Refer to graphs, charts, and line drawings as text-figures. Make the abbreviations on text-figures identical to the abbreviations used in the text and legends. Symbols and lettering should be large enough to be legible if reduced. Glossy prints or original drawings in black ink are acceptable; orient vertically instead of horizontally.

FIGURES: Refer to photomicrographs and photographs as figures. Figures and their legends should fit a 7.5- by 9-inch dimension. Calculate that nine typewritten lines of legend will require 1 inch of vertical space. Type figure legends on a separate sheet and identify in the legend any lettering used on the figure. Trim photographs to show only important areas. Do not number face of photographs; use the back or overlay to indicate the top and number of each. Printed indicators may be included on photographs; do not use hand-drawn indicators. *Insert internal scale markers on all photomicrographs.* Color photographs must be grouped as a single plate. For color reproduction, submit both color transparencies and high-quality black and white reproductions. The need for color must be documented before it will be considered.

REFERENCES: Use any recent issue of the Journal as a style guide for reference lists. Number references in order of citation in both text and reference list. For periodicals, provide author(s), title of paper, journal, year, volume, and first and last page numbers. For books, give the author(s), title, name(s) of editor(s), location and name of publisher, year, pertinent chapter or section title, and page numbers. Follow *Index Merdicus* for punctuation and abbreviations. Citations of papers in preparation or submitted for publication, unpublished observations, and personal communications should be noted parenthetically in the text. Do *not* include them in the reference list. The accuracy of all references is the responsibility of the authors and not of the editorial staff.

LETTERS TO THE EDITOR should pertain to recent articles in the Journal and should not contain new data unless relevant to the discussion of a particular paper. The authors addressed will be invited to reply to comments before correspondence is published. Letters will be edited by the Staff, subject to contributor approval.

FURTHER DETAILS on the preparation of manuscripts are set forth in the document "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" prepared by the International Steering Committee of medical editors (*see* Am Rev Respir Dis 1979;119:3-10/Ann Intern Med 1979;90:95-99/Br Med J 1979;1:532-535/ or Lancet 1979;1:428-430).

Sidney Weinhouse[1,2]

What are Isozymes Telling Us About Gene Regulation in Cancer?[3,4]

There is an increasing recognition that cancer is associated with abnormalities of gene regulation, manifested by misprogramming of protein synthesis. Whether or not this phenomenon is causal, consequential, or incidental to the neoplastic transformation, it is interwoven throughout the whole fabric of cancer biology and may therefore be a key to the long-sought molecular basis of neoplasia. It encompasses virtually every means we have of identifying gene products, including antigens, polypeptide hormones, membrane glycoproteins, growth factors, and of course enzymes, the subject of this essay.

Because enzymes constitute the machinery of the cell, they are obvious sites of functional importance in tumor growth and metabolism. For this reason they have been the focus of several generations of biochemical effort which, unfortunately, has resulted in an unwieldy mass of data that have confused rather than illuminated our conceptions of the enzymatic basis of the neoplastic process. Early attempts to relate neoplasia to changes in enzyme activity are highlighted in the enzyme convergence hypothesis of Greenstein (*1*). Potter has spent a lifetime career in a study of the significance of enzyme composition in tumors and recently summarized his ideas as they evolved from the original enzyme deletion hypothesis to his current views on cancer as an aberration of embryonic development (*2*). More recently, Weber (*3*) has brought a degree of order into the relationships between tumor growth rates and enzyme activity. He classified a large number of enzymes, primarily of carbohydrate and nucleotide metabolism, into anabolic and catabolic species and demonstrated a good correlation in liver and kidney neoplasms between ratios of the activities of the so-called anabolic and catabolic enzymes and their growth rates.

ROLES OF ISOZYMES[5]

The development of highly sensitive methods of protein separation and identification led to the realization that many enzymes exist in multiple forms that catalyze the same reaction but differ in chemical and kinetic properties (*4*). The existence of enzymes structured specifically for individual organ function has added a new dimension to our conception of metabolic regulation. Since it is presumed (though not always proved) that isozymes are products of different genes, they provide additionally, elegant opportunities for understanding the genetic basis of metabolic dysfunction. As a result, a renewed interest is being kindled in studies on the enzymatic machinery of the cancer cell, bringing with it the discovery of a host of isozyme alterations in tumors (*5–8*). These studies have had a dual impact—not only have they broadened our insights on the molecular basis of tumor metabolism, but also they have brought isozyme alterations within an already impressive conceptual framework built from a variety of other abnormalities of genetic regulation in cancer.[6]

TWO EXAMPLES OF ISOZYME ALTERATION IN HEPATOMAS

Because of the rich diversity of enzymes catalyzing the many specialized functions of the liver, this organ and its neoplastic counterpart, the hepatoma, are especially advantageous model systems for comparative studies of isozyme composition. Happily also, there are available the Morris hepatomas (*9*), a spectrum of chemically induced, transplantable rat tumors ranging widely in growth rate, degree of differentiation, and in their retention and loss of hepatic functions. Although much of our knowledge of isozyme alterations is thus somewhat narrowly based on the rat liver-hepatoma model, several clearcut isozyme alterations in nonhepatic organ–tumor systems, attest to the generality of this phenomenon.

Aldolase

Aldolase is especially noteworthy because it was the first

[2] Thanks are due to Jennie B. Shatton, Albert Williams, and Harold P. Morris for their contribution to this work.

[3] Received September 3, 1981.

[4] The experimental work of the author is supported by Public Health Service grants CA-12227 and CA-10916 from the National Cancer Institute and by grant 74-BC from the American Cancer Society.

[5] A detailed discussion of the definition and properties of isozymes is beyond the scope of this brief essay. The reader is referred to the commission on biochemical nomenclature of the International Union of Biochemistry (Enzyme nomenclature. Amsterdam: Elsevier Sci Publ, 1972:24). The term isozymes is restricted to enzymes that are products of different genes and to heteropolymers thereof, where applicable. The term excludes those enzymes derived by chemical modification or by allosteric modification through interaction with substrates or effectors.

To save space, the reference list is largely confined to review articles, from which references to the primary literature can be obtained.

[6] Isozymes of glucose-6-phosphate dehydrogenase have played an important part in establishing a clonal origin for human tumors (Fialkow PJ. Clonal origin of human tumors. Biochim Biophys Acta 1976; 458:283-321). However, this topic is not covered in this paper.

Editor's note: Periodically, the Journal publishes solicited guest editorials as a means of transmitting to investigators in cancer research the essence of current work in a special field of study. The Board of Editors welcomes suggestions for future editorials that succinctly summarize current work toward a clearly defined hypothesis regarding the causes or cure of cancer.

to have its isozyme composition studied in tumors; and it exemplifies the many other subsequently revealed isozyme alterations in neoplastic tissues. It occurs in cells as a tetramer, the composition of which depends on the relative abundance of the subunit isozymes (*5*). These subunits are denoted as A, B, and C. Isozyme C appears very early in embryonic development and is accompanied, and ultimately replaced to a large extent, by isozyme A in the fetus. Isozyme A persists into adulthood in most organs and is accompanied by isozyme C in adult brain. In contrast, isozyme A, the major form in fetal liver, is essentially replaced completely by isozyme B in the adult liver. The B-isozyme is kinetically geared for two highly specific liver functions: the utilization of fructose and the conversion of triose phosphates to hexose phosphate in the synthesis of glucose.

The first clear-cut demonstration of enzyme alteration in cancer can be credited to Schapira (*5*), who observed a striking change in the properties of serum aldolase in several human diseases. The serum enzyme resembled that of muscle aldolase in some muscular diseases and resembled that of liver aldolase in hepatitis or liver glycogen storage disease. Thus the serum isozyme reflected its probable derivation from the diseased tissue. However, in liver tumor patients the serum had the muscle isozyme. Subsequent studies by Schapira and other investigators revealed that liver neoplasms, in contrast with adult liver, consistently exhibit an aldolase isozyme pattern resembling that of fetal liver or nonhepatic adult tissues with preponderance of isozymes A or A and C (*5*). My colleagues and I found (*10*) for example, that aldolase B is lost to a varying degree from the "spectrum" of Morris hepatomas, depending on their growth rate and degree of dedifferentiation; in rapidly growing, poorly differentiated liver tumors we found aldolase B to be completely replaced by aldolase A.

Hexokinases

Three hexokinase isozymes termed I, II, and III are present in varying proportions in fetal and adult tissues. Shortly after birth, a fourth form, IV, appears in liver (*11*). Because of its specificity toward glucose, it has been termed glucokinase. It is endowed with several special properties, two of which are extremely important to hepatic glucose metabolism; a low affinity for glucose, which ensures the physiologically appropriate hepatic glucose uptake only during hyperglycemia, and a marked responsiveness in activity toward glucose and dependence on various hormones, particularly insulin (*11*). As with aldolase B, glucokinase is lost to varying degrees in hepatomas, depending on the growth rate and and degree of dedifferentiation, and is replaced completely in fast-growing, poorly differentiated hepatomas by one or more of the other three hexokinase isozymes that are present in fetal liver (*12*).

FETAL ISOZYME EXPRESSION IN HEPATOMAS

These examples illustrate two noteworthy features of isozyme alterations in cancer. In each instance, an isozyme geared kinetically for specific adult liver functions is lost and is replaced by isozymes with different kinetic properties, presumably only geared for efficient substrate utilization. This type of change can be perceived as a molecular foundation for the loss of host control over tumor growth that characterizes cancer. The second notable feature is that isozyme alterations cut both ways. While fetal isozymes appear, there is also a loss of adult forms. Thus not only is there an apparent reactivation of genes that were active during fetal stages but were inactivated during normal embryonic development; there is also a suppression of genes coding for adult liver enzymes.

As isozyme alterations in tumors unfold, it is becoming increasingly evident that fetal isozyme expression in hepatomas is a wide-ranging general phenomenon. In a recent review, Ibsen and Fishman (*13*) collected 22 instances of fetal isozyme expression in tumors of various types. These are listed in table 1. It is obvious that in liver tumors there is a massive switch in enzyme protein expression; it is likely that many more remain to be discovered. For those proteins that appear in cancer and are also found in the fetus and various embryonal-derived tissues such as the trophoblast and the placenta, Fishman (*14*) has proposed the term oncodevelopmental proteins. The widespread interest in such tumor-associated proteins, which reflects their biologic and potential diagnostic importance, has given birth to an International Society of Oncodevelopmental Biology.

Although most of our information has been gained thus far from studies on hepatomas, the shift to fetal isozyme expression does occur also in nonhepatic tumors. Schapira (*5*) observed fetal aldolase C in human rhabdomyosarcoma; Failly-Crepin and Uriel (*15*) reported the presence of a fetal brain carboxyl esterase in murine teratocarcinoma; and Omenn and Hermodson (*16*) found that whereas both fetal and adult normal human brain have the same phosphoglycerate mutase isozyme as do relatively benign brain tumors, highly malignant astrocytomas have the muscle- or hybrid-type isozymes. Farron et al. (*17*) observed fetal muscle pyruvate kinase III in a rat rhabdomyosarcoma, and my colleagues and I (*18*) found fetal muscle creatine kinase B in rat rhabdomyosarcomas. Herzfeld and Greengard (*19*) have reported fetal patterns of enzyme composition in colon and lung neoplasms. Further studies will surely yield more examples of fetal isozyme expression in other experimental tumor models.

Among the enzymes listed in table 1, several are especially worthy of mention.

Alkaline Phosphatase

This enzyme has clinical importance because the genotypic forms and their several variants in human cancer are being explored as diagnostic aids (*14*). There are at least three distinct genotypic forms in human tumors and in plasmas of cancer patients. One of these is present in hepatomas and, though not found in fetal liver, is present in fetal and adult intestine. Another isozyme is present at all phases of embryonic development. A third, the so-called Regan isozyme seen commonly in ovarian, testicular, and pancreatic tumors, is most prominent in term placenta but not in the fetus.

γ-Glutamyl Peptidotransferase

A striking example of the resurgence of a fetal isozyme in

TABLE 1.—*Isozymes expressed in hepatomas and various other tumors and in embryonal, fetal, or placental tissue*[a]

Isozyme	Developmental stage of expression	Neoplasms expressed in:
Aldolase A	Fetal liver and gut	Hepatoma, duodenal, adenocarcinoma
Aldolase C	Embryonic liver, fetal muscle	Hepatoma, rhabdomyosarcoma
Pyruvate kinase K	Fetal liver, muscle, brain	Hepatoma, rhabdomyosarcoma, brain tumors
Glycogen phosphorylase (low Pi)	Fetal liver, placenta	Hepatoma
Hexokinase II	Fetal liver, placenta	Hepatoma
Hexokinase III	Neonatal liver, placenta	Kidney tumors, mammary tumors, rhabdomyosarcoma
L-Glycerol 3-phosphate dehydrogenase (anodal form)	Embryo, early fetus	Ascites tumors
Alcohol dehydrogenase (anodal form)	Fetal liver	Hepatoma
Branched chain amino acid amino-transferase III	Placenta	Hepatomas
Glutaminase K	Fetal liver	Hepatoma, mammary tumors
Histaminase	Fetal liver	Various tumors
Carbamyl phosphate synthetase II	Fetal	Hepatoma, mammary tumors
Ornithine decarboxylase (low Km)	Fetal	Various tumors
tRNA methylases	Fetal liver	Hepatoma, other tumors
CDP-reductase	Fetal liver	Hepatoma
Thymidine kinase, cytoplasmic	Fetal liver, gut	Hepatoma, gastrointestinal neoplasms
Uridine kinase II	Fetal liver	Hepatoma, leukemia
DNA polymerase γ	Fetal liver	Hepatoma
dCMP deaminase	Fetal liver	Hepatoma
Glucosamine 6-P synthetase (low Pi)	Fetal liver	Hepatoma
Hexosaminidase (fast)	Fetal liver	Hepatoma
Alkaline phosphatase (Regan)	Placenta	Many tumors
Alkaline phosphatase (hepatoma form)	FL amnion cells, fetal intestine	Hepatoma
Alkaline phosphatase (non-Regan)	Chorion, fetal	Many tumors
γ-Glutamyl transpeptidase (fetal)	Fetal liver	Hepatoma
Arylamidase	Placenta	Hepatoma

[a] Data from Ibsen and Fishman (*13*). Reprinted courtesy of Elsevier/North Holland Biomedical Press.

tumors is γ-glutamyl transpeptidase. This enzyme is bound to the plasma membrane, and it is normally low in adult rat liver but very high in fetal liver and chemically induced hepatomas. According to Fiala (*20*), who originally noted the dramatic increase of this enzyme in tumors, it appears very early in the liver (within 10–20 hours) after carcinogen administration. Its functional role in amino acid transport, particularly in the kidney, and in the formation and breakdown of glutathione has been pointed out recently by Allison and Meister (*21*).

Pyruvate Kinase

This enzyme is located at a strategic site in the pathways of carbohydrate metabolism and, because it utilizes ADP as a substrate and yields ATP as a product, plays a particularly important role in the energy transduction associated with glucose metabolism. Sixty years ago Otto Warburg discovered that certain tumors avidly utilize glucose aerobically and in common with normal tissues utilize less glucose in the presence of oxygen than in its absence; a phenomenon he termed the Pasteur effect. This name was based on an observation made by Pasteur some 100 years earlier that when yeast is exposed to oxygen it ceases to ferment glucose. The significance of the high aerobic glycolysis of tumors and the Pasteur effect have been perennial and still unresolved subjects of much experiment, discussion, and controversy (*22*). These complex interrelationships between oxygen and glucose utilization in tumors may be mediated in part at least by changes in the activities and isozyme composition of pyruvate kinase. Since this enzyme competes for ADP with the phosphorylation of ADP to ATP that is also coupled with respiration, the reciprocal relationship between respiration and glucose utilization implied in the Pasteur effect is understandable. For the same reason, a high pyruvate kinase activity, which typifies many tumors, can be perceived as a major factor in their high glycolytic activity. Evidence for such a role of pyruvate kinase has been obtained by us in collaboration with Gosalvez et al. (*23, 24*). By manipulating the relative activities of pyruvate kinase and mitochondrial respiration, competition for ADP between those systems was demonstrated (*23*); and further studies in which pyruvate kinase was specifically inhibited in Ehrlich ascites cells (*24*) provided further suggestive evidence that the replacement of a tightly controlled hepatic pyruvate kinase by a high activity of the fetal form may be responsible for the high glycolytic activity of the rapidly growing, poorly differentiated hepatomas.

OTHER TUMOR-ASSOCIATED PROTEINS

If isozyme alterations were the only manifestation of altered gene regulation, they would represent merely one more peculiarity to be added to an already large array of perplexities that contribute to the mystery of cancer. However, it is clear now that isozyme alterations are merely one manifestation of what is evidently a wide-ranging phenomenon, encompassing virtually every means we have of identifying proteins. Immunologic methods applied over nearly a century have identified a host of tumor-associated antigens, many of which are found in normal fetal tissues. Some of these, for example carcinoembryonic antigen and α-fetoprotein, figure prominently in diagnosis of cancer and monitoring of treatment (*25–27*). Another striking example of transformation-associated gene activation is the many changes in enzyme activities, cell composition, and metabolism of somatic cell hybrids resulting from transformation by simian virus (*28*).

Plasminogen activators are proteolytic enzymes that convert plasminogen to plasmin and may be responsible for tumor invasiveness. They occur in the early embryo and are produced and secreted from transformed cells in culture (*29*). The synthesis and secretion of angiogenesis factor(s), upon which the developing embryo depends for the ingrowth of capillaries from nearby blood vessels are also required for growth of solid tumors (*30*). Tumors are generally less fastidious in their requirements for growth in culture than normal cells, a property due, according to Todaro and Delarco (*31*), to acquisition of the ability of these cells to synthesize their own growth factors.

A bizarre phenomenon, increasingly recognized to occur commonly in human nonendocrine tumors is the ectopic production of polypeptide hormones. Virtually every known polypeptide hormone has been identified as a tumor product. Recently Imura (*32*), and earlier Levine and Metz (*33*), pointed out an underlying pattern according to which the hormones produced can be classified consistent with the embryologic background of the tissue of origin. As seen in table 2, a wide variety of tumors in Group I arise from so-called APUD (amino acid precursor uptake and decarboxylating) cells, considered to be of ectodermal origin, whereas tumors of Group II arise from tissues derived from endoderm and mesoderm. In addition, some tumors, classified in Group III, produced polypeptides, which may not be ectopic in the strict sense because the normal tissues of origin are unknown.

Thus the ectopic production of polypeptide hormones by tumors reflects some limitations already imposed upon gene expression of cells at an early stage in embryogenesis. Once considered rare, the development of ultrasensitive methods of radioimmunoassay has rendered ectopic hormone production so common as to suggest that it may occur with all tumors (*34*). It is likely that these ectopic hormones, as well as other hormones waiting to be discovered, may well be responsible for the many otherwise inexplicable effects of tumors on host metabolism and behavior (*35*).

TABLE 2.—*A classification of hormone-producing tumors*[a]

Group	Hormones produced	Common tumors
I	ACTH, LPH, α-MSH, CLIP	Oat-cell cancer (lung)
	β-endorphin, γ-MSH	Carcinoid
	Vasopressin, oxytocin, neurophysin	Thymic cancer
	Calcitonin	Islet-cell cancer
	Other APUD hormones (CRF, GRF, VIP, somatostatin, gastrin, etc.)	Medullary thyroid cancer
		Pheochromocytoma
II-A	PTH	Renal cancer, hepatoma
		Epidermoid cancer (lung)
II-B	GH	Lung cancer
	PRL	Gastric cancer
II-C	hCG	Large-cell cancer (lung)
	hCS	Hepatoma
III[b]	Erythropoietin	Hepatoma, cerebellar hemangioblastoma
	Colony-stimulating factor	Epidermoid cancer etc.
	NSILA (insulin-like growth factor)	Mesodermal tumor, hepatoma, etc.

[a] Data are from Imura (*32*). Reprinted courtesy of Academic Press.

[b] Group III tumors may not be "ectopic" hormone-producing tumors in a strict sense.

SOME ECTOPIC ISOZYMES

Ectopic protein expression is not entirely confined to polypeptide hormones. We recently observed that neoplasms of rat liver, kidney, and brain contain the M-form of creatine kinase characteristic of adult muscle, as well as the B-form, which is the only detectable isozyme in the tissue of origin (*18*). Phosphoglycerate mutase is another enzyme in which the sole form in human brain is the B-isozyme, whereas highly malignant brain tumors also carry the adult muscle, M-form (*16*). Tanaka et al. (*36*) observed the ectopic occurrence of the adult liver form of phosphofructokinase in several nonhepatic neoplasms. No doubt other examples are awaiting discovery.

LOSS OF ADULT LIVER ENZYMES

Another facet of enzyme alteration in tumors can be considered to be within the realm of fetal expression—namely, the loss in hepatomas of many adult liver enzymes that are also normally low or absent in fetal liver. This category includes for the most part enzymes participating in specialized adult liver functions such as gluconeogenesis, fructose metabolism, and fatty acid oxidation. In a study of 82 enzymes occurring in normal adult rat liver, Knox (*37*) found that 32 of these had low or negligible activity in fast growing hepatomas. Of this number, 24 also had low or negligible activity in fetal liver. Of the 50 enzymes that retained high activity in fast growing hepatomas, 42 of these also had high activity in fetal liver.

In a comprehensive study of human intestinal and pulmonary tissue and their neoplastic counterparts, Herzfeld and Greengard (*19*) found a close resemblance in enzyme pattern between fetal and neoplastic tissues but a lesser correlation with the normal tissues. Though these observations are not as striking as the resurgence of fetal liver-associated isozymes in hepatomas, they emphasize further the similarities of enzyme expression shared by fetal liver and rapid-growing tumors.

SOME CONCERNS ABOUT SIGNIFICANCE OF ISOZYME ALTERATIONS

The cancer problem is characteristically plagued by uncertainties, and the alterations of isozyme expression in hepatomas are not without their ambiguities. First is the question of definition. It is implicit in considering isozyme alterations as abnormalities of gene expression that isozymes are products of different genes. This is not generally easy to establish and in many instances is an article of faith rather than fact. The growing recognition of enzyme variants and the existence of post-translation modifications of proteins necessitate caution in assuming the existence of true isozymes without definitive evidence. Second, alterations in enzyme activities in hepatomas occur against a background of normal physiological variation. Many isozymes of adult liver undergo substantial changes in activity in response to normal dietary and hormonal alterations. It is important to establish, therefore, that the observed alterations in tumors are not merely consequences of metabolic changes that may occur in tumor-bearing animals. Third, isozyme alterations are almost never all or none. Fetal isozymes generally do not disappear completely from adult liver, and adult liver isozymes generally do not disappear completely, even from the least differentiated hepatomas. Moreover, enzymatic differentiation follows separate temporal sequences in different tissues; what may be a fetal liver isozyme also may be an adult isozyme of other tissues. Another question that needs resolution concerns tumor heterogeneity. In many instances we are not sure whether isozyme alterations are due to true changes in isozyme composition of a homogeneous cell population or to differences in the cell populations comprising the tumor. Granting that isozymes are truly products of different genes, another question concerns the extent to which the activity levels observed are due to variations in rates of synthesis and degradation, or to factors concerned with the activation or inactivation of preexisting protein structures. These questions are coming to the fore increasingly with the development of highly sensitive enzyme radioimmunoassays.

In comparing adult liver or hepatomas with fetal liver, one should also note that prior to birth there is a change in cell population. Early in fetal development the liver contains a substantial portion of hematopoietic cells. However, at 1–3 days before birth, when fetal liver is usually taken for enzyme assays, the large majority of cells are hepatocytes (*37*).

Finally, a thoughtful assessment of abnormal gene regulation in cancer must also consider that the expression of fetal or ectopic proteins may occur fleetingly during cell proliferation induced either by partial hepatectomy or by growth of liver cells in culture (*38*). The crucial difference is of course that in hepatomas the change persists. Nonetheless, any conclusion as to the significance of isozyme alterations must be tempered by the possibility that those changes may be the result rather than the cause of cell proliferation.

Despite the many above-mentioned uncertainties, there is no doubt that cancer is associated with a massive switch in protein composition. The expression of fetal and ectopic proteins by tumors provides a plausible explanation for the many metabolic peculiarities of cancer cells and their effects on the host, and their functional significance should be a promising direction for future progress in the diagnosis and management of human cancer. More important, perhaps, is what these phenomena are trying to tell about the molecular nature of the neoplastic transformation. In the following concluding paragraphs a few personal reflections are presented, without attempting the virtually impossible task of reviewing the voluminous speculations on the role of gene regulation in cancer.

Genetic Versus Epigenetic Mechanisms

One of the long-standing unresolved problems is the significance of somatic mutation in cancer causation. The association between increased cancer incidence in a variety of genetic disorders and chromosomal abnormalities (*39*), the increasing recognition of DNA as a target of oncogenic viruses, radiation, and chemicals, the role of deficiency or infidelity of DNA repair in cancer causation (*40*), and the close correlations between carcinogenesis and microbial mutagenesis (*41*) provide a body of such compelling evidence as to place the somatic mutation hypothesis in the status of dogma.

It is ironic, therefore, that equally compelling evidence exists for an epigenetic process of cancer induction to which the misprogramming of isozyme and other protein expression adds strong support. Whether these proteins are identified as isozymes or antigens or polypeptide hormones, it is very important to recognize that these are not new proteins. They are mislocated either temporally or geographically and are therefore assumed to be products of genes that are not new. However, these proteins are newly activated by some mechanism that overcomes the normally rigid process by which genes are selected for expression or repression in each tissue during normal embryonic development. Discussions and speculations on epigenetic mechanisms in neoplastic development may be found in several recent papers (*42–45*).

A substantial proportion of the DNA in the genome probably serves a regulatory function, and we might assume that mutations leading to cancer occur in regulatory genes. This otherwise plausible assumption is not compatible, however, with a body of convincing evidence that the genome of at least some cancer cells can survive the neoplastic transformation with an intact, totipotential genome.

The genomes of many-times-transplanted frog or mouse cancer cells retain all of the encoded information and the capability, under appropriate circumstances, for normal embryonic development and to yield normal viable progeny with the genetic properties of the original tumor host intact (*42–46*). Plant tumors grown in culture for many generations, can in the proper environment, also undergo redifferentiation to yield plants that can flower and produce seed and ultimately new plants that are genetically indistinguishable from the original plant tumor host (*47*). This degree of genetic fidelity toward one of life's most highly orchestrated processes hardly seems compatible with a somatic mutation, whether in genes that code for structural, functional, or regulatory proteins.

Additionally, there is an increasing awareness that the neoplastic transformation may not be as immutable as was generally believed. Partial temporary redifferentiation of cultured transformed cells by addition of chemicals (*48*) or in some instances merely by change in temperature are common phenomena (*49*); there are rare but well-documented instances of "spontaneous" reversion of human cancers (*50*).

A pervasive question is why is there a preferential if not obligatory activation of embryonal or fetal genes in cancer? A plausible hypothesis in the light of current knowledge is that of Uriel (*51*). He has proposed that cells attacked by carcinogens have to undergo retrodifferentiation to a partially differentiated state as a normal physiological response to damage, thereby enabling cells to assume their fully differentiated state by way of normal regenerative mechanisms.

As Uriel points out, the regeneration of limbs, tails, and other organs, a process that occurs commonly in amphibia following resection, is preceded by a retrodifferentiation of those cells destined for redifferentiation to the new organ. Apparently, a reversion to what appears to be an embryonic stage of development is a general requirement for a normal reordering of gene regulation following tissue injury. This retrodifferentiated state probably accounts for the transitory appearance of fetal gene products during liver regeneration (*38*). When, however, a cell becomes transformed, differentiation is not completed, and the regulatory restraints that normally operate would not be fully functional. Under these circumstances, control of cellular proliferation would be impaired. Failure to reach the fully differentiated state would probably result in an unstable genome. It is conceivable that such an unstable genome, lacking host control of cell division, would lead to variability of progeny, thus accounting for the diversity of tumor phenotypes. Selection of such variable progeny for rapid growth could then account for tumor progression (*52*), an intractable common feature of human cancer, trending inexorably toward increased growth rate, autonomy, anaplasia, and resistance to treatment. Potter (*2, 53*) has over many years also envisioned the neoplastic condition in terms of an inability of cells to complete the full program of differentiation that is required for harmonious integration of tissues into the totality of functions in the whole organism. His view, expressed in the aphorism, "Oncogeny is blocked ontogeny," exemplifies the growing recognition that cancer is associated with abnormalities in the maintenance of the fully differentiated state.

With such strong evidence for and against the somatic mutation hypothesis, the question is, How can this situation be reconciled? What kind of change in DNA can be induced that will not involve a change in its primary structure, yet will lead to a quasi-permanent disruption of the normally rigid selective mechanisms for gene expression. Without mutation in the strict sense, how can the relationships of regulatory to structural genes be so altered as to yield new stable conformations that lead to an abnormally differentiated state with the acquisition of proliferative potential? These questions are of course central to our understanding of developmental biology, and they place the cancer problem directly within this as-yet-underdeveloped field. It would appear that somewhere within the temporally programmed modulation of gene readouts involved in normal embryonic development leading to the fully differentiated state there probably lies the key to the understanding of the neoplastic transformation.

Although little is yet known of the molecular processes involved, a great deal of effort is currently directed to mechanisms of gene transcription and translation. Some particularly promising clues to regulation of genomic expression follow from recent findings on a possible role of macromolecular methylation. Forrester and Hancock (*54*) have proposed that methylation of a repressor protein is required for activity in normal differentiation. Methylated bases, e.g., 5-methylcytosine in DNA, have been suggested for a regulatory role in eukaryotic as well as prokaryotic cells (*42, 55, 56*), and tRNA methylation also has been implicated in differentiation and neoplasia (*57*). The pace of activity in these and other studies of molecular mechanisms of gene regulation bode well for early answers to the enigma of cancer.

Single Oblique-View Mammography for Periodic Screening for Breast Cancer in Women[1,2]

Bengt Lundgren, *M.D.*,[3] *and* **Anders Helleberg**, *M.D.*[4]

ABSTRACT—A population, originally 6,845 women, 40 years of age and over, was screened for breast cancer by single oblique-view mammography in 1974, 1977, and 1980. Of the 5,789 women remaining in their parish in 1980, 94% had attended the screening at least once. Of 111 breast cancers diagnosed in the 6.25-year study period, 78% were detected at screening, 15% as interval cancers, and 7% among nonresponders. Sixty-three percent of the women had tumors in clinical stage I, and 59% had tumors less than or equal to 10 mm. The predictive value for biopsy recommendations by mammography was 78%. This method was considered very suitable for screening. In the older age groups there was probably some overdiagnosis of cancers that would never have become symptomatic.—JNCI 1982; 68: 351–355.

The most important question still to be definitely answered regarding screening for breast cancer is that of screening's impact on breast cancer mortality. Breast cancers vary widely in growth rates, and growth rate may strongly influence the outcome of treatment. The fast-growing cancers probably metastasizing early may be beyond any type of treatment, whereas the very slow ones perhaps need not be treated at all. Probably, an intermediate tumor group exists that is influenced positively by early treatment, and screening would be beneficial for this group. However, if screening and early treatment were proved to have no effect on mortality, the concept of biologic predeterminism would be true. But important evidence contrary to this concept exists, of which the most convincing is the Health Insurance Plan of Greater New York (HIP) study showing long-term reduction of mortality as a result of screening. (*1*)

Another important point in the evaluation of screening programs is whether high attendance rates can be maintained through several repeat screenings. The falling off of participation to unprofitably low levels could be one reason to abandon this procedure (even if the screening were well performed in other respects) because then the impact of screening on the disease in the population would be too small to merit its use.

Also, overdiagnosis of cancer is conceivable in elderly patients and/or in those with very slow-growing tumors.

Beginning in 1974, population screening by single oblique-view mammography has been performed in an increasing number of regions in Sweden. The technique was developed in Gävleborg County, starting with a pilot study (*2*) in the town of Sandviken on a population since then closely followed. This population was screened a second time in 1977 (*3*) and a third time in 1980. Actually, all the females of the county 40 years and older were screened at least once. This report deals with the pilot study population; it emphasizes the third screening and refers back through the period of 6.25 years from the start of the program. Our aims were to study participation and detection rates, incidence of breast cancer in the population, tumor stages, and the likelihood of overdiagnosis and, if possible, to reach a conclusion regarding the optimum interval time for effective screening by single oblique-view mammography.

The present study was not randomized, since it was extended from a methodic development project. However, randomized and controlled screenings to study effects on breast cancer mortality have been used by this method in Kopparberg County since 1977, in Östergötland County since 1978 (*4*, *5*), and in the city of Stockholm since 1981.

MATERIALS AND METHODS

The original population defined in March 1974 was comprised of 6,845 women 35 years or older living in the urban parish of Sandviken, a small industrial town in middle Sweden. In August 1977, when the second screening was begun, 6,231 remained alive and in the study area, 315 women had died, and 299 had moved out of the parish. The average time between screenings was 3.4 years, and the average yearly decline in number of women was 2.6% (*6*).

In January 1980 a new census was done (table 1); 5,789 women, then aged 40 years old and above, remained in the parish. The average yearly decrease in number of women since 1974 was 2.7%. The greatest change was, naturally, in the oldest age group (>69 yr old), where deaths accounted for most of the population decrease, and the next greatest change was in the youngest age group, where relocation accounted for most of the 15% decrease.

The screening method in 1980 was that of the previous screening, i.e., single oblique-view mammography (*2*, *7*) (one X-ray film of each breast available to the reader). Physical examination was not done at screening. The participants were asked if they had felt any lumps; if they had, clinical examination was prescribed, irrespective of mammography results. Also, in instances of suspicious mammography findings, patients were clinically examined.

The screening was done by two radiographers in a mobile unit. Each full working day about 125 women were invited to participate, and normally 95–105 of them attended. They were invited by computer-printed letters with appointment

[a] Decrease in numbers in 1974–77 and 1974–80 caused by deaths and relocation out of the study parish.

times. The exposed X-ray films were sent to the central screening unit at Gävle Hospital, where they were processed and read the day after the examination. Letters reporting good health were normally received by the participants on day 2 after examination. If findings at mammography screening were doubtful, a complete three-view examination was done; if suspicions still remained, the patients were referred to the Gävle Hospital breast unit for clinical examination, upon which a few patients were found to have benign conditions, usually cysts, and were then given reports of good health. The remaining patients usually underwent surgical biopsy. Nonpalpable lesions were first localized by needle and hook and then received injections of methylene blue dye. Specimen radiography was always performed. If the suspicious lesion consisted of microcalcifications, the paraffin-embedded specimens were X-rayed to substantiate the microscopic findings.

Information on growth rates of the cancers in the present study is incomplete. A prerequisite for such knowledge is that previously recorded mammographies are available for all cancer cases. However, such mammographies were not available at the first screening occasion and for nonresponders. The rate of growth can be estimated for cancers that generate at least a moderately well-defined tumor shadow. For cancers that are visible as microcalcifications only, the size of the tumors cannot be determined. In several cases growth rates could be calculated, however.

The curative treatment varied. Some of the oldest patients were given Tamoxifen orally as the only therapy, without excision of the tumors. In these cases there were positive cytologic cancer diagnoses. On some patients tylectomy and exploration of the axilla were done, without subsequent radiotherapy. The most "radical" treatment was total mastectomy with exploration of the axilla.

The X-ray equipment was a Philips Mammodiagnost. Kodak-Pathé NMB film was used with Kodak min-R screens. The average absorbed radiation dose was 0.7 mGy (70 mrad).

RESULTS

Participation.—Of the 5,789 women remaining in 1980, aged 40 years and over, 82% participated at the third screening. Table 2 shows the participation of these women at all three screenings. The attendance rate of women at the ages below 70 years old was over 90% on all three occasions and much lower in those at ages over 69 years old.

Table 3 demonstrates numbers and rates of women participating in the screening once only, twice, or three times. Of the total population, the percentage of participants with at least one attendance was 94% for those 40 years old or more and 96% for those 40–69 years old.

Of the 1,057 nonparticipants at the third screening, 90 entered the Gävle Hospital breast unit in 1979 or the first half of 1980.

Referrals and detections at third screening.—Table 4 shows numbers and rates of referred patients and cancer cases. The cancer detection rate among participants over 40 years old was 4.4 per 1,000 and among those 40–69 years old, 3.2 per 1,000; the predictive value for patients referred from screening to clinical examination was 55% and 44%, respectively. In all, 38 patients were referred (0.8%), of whom 9 were found to have clinically benign lesions, mostly cysts. Of the remaining 29 patients, 21 had histopathologically

verified breast cancers and 8 had benign lesions at surgical biopsy (PV, 72%).

Thirty-one patients were referred by mammography only, of whom 21 had cancer (PV, 68%). One of the cancer patients had felt a lump; the other patients were nonsymptomatic. A further 7 patients had reported lumps but had normal mammography and physical examination results. Of the 31 patients referred by mammography, 4 had benign lesions diagnosed at clinical examination, and biopsy was recommended in 27 patients (PV, 78%), 21 of whom had cancer. There were 4 noninvasive ductal cancers (TIS); 11 were stage I, 4 were stage II, and 2 were stage III invasive cancers. The stage III cancers (T2aN2M0 and T4bN2M0) were considered inoperable. Of the remaining 19, only 1 had axillary metastases diagnosed after biopsy.

Breast cancer detections.—The stages (according to the TNM system) of all 111 cancers detected during the study period, i.e., at screening, at follow-up of suspicious cases, during intervals between screenings, and among the nonresponders, are shown in table 5. At screening, 7 of 86 (8%) of the cases detected were in stages III and IV, compared to 6 of 16 (38%) of the interval cases.

Sizes of the tumors detected at screening, measured as the largest diameter in the biopsy specimens or in some cases in the radiographies, are shown in table 6. The total rate of noninvasive and invasive cancers 10 mm or less was 59%.

Table 7 shows the ages of all breast cancer patients diagnosed in the population since the start of the first screening and includes screening detections, interval cases, and cases among nonresponders.

Overdiagnoses.—There is an obvious possibility that some cases of cancer detected in a screening would never have developed into clinically detectable tumors during the patient's normal life expectancy; some may not be lethal, given even several decades of growth. Our hypothesis is that this could occur only at an initial screening, when no evidence exists about the biologic behavior of the individual tumors. At subsequent screenings, there will always be available "base-line" mammographies, and only tumors with radiologically verifiable growth will be diagnosed. A way to gain more solid evidence on this point was tested in the present study, although the number of cancer cases was small.

Table 5.—*Stages according to the TNM system of all tumors detected at three screenings, during intervals, and among nonresponders*

Stage	No. of cancer cases detected

Text-figure 1.—Cancer incidence variations caused by three screenings.

Text-figure 1 demonstrates schematically the incidence of breast cancer in the study population during the study period. On the first screening a rather high rate of prevalent cases was detected, giving 4.3 times the expected incidence in 1974 (*2*), which lowered at the two following screenings. In the interval years the incidence rates were well below the average expected (*6*). Average yearly observed standardized incidence rates were calculated for the whole period (A) and for the period after the first screening (B), and these were compared to the expected standardized national incidence.

Table 8 shows the total average rate of observed incidence (detections at screening, interval cases, and cases among nonresponders) against expected incidence for period A, estimated on a standard population with the use of the census from the midpoint screening in 1977. Only those of ages up to 69 years old were tested, and the age group 35–39 years old was too small both in number of persons and cancer cases to be useful. It would seem that over this period 1.5 times as many cases were detected as expected; in the age group 60–69 years old, twice as many as those expected were detected.

Table 9 demonstrates period B studied in the same manner. When the first screening occasion was excluded, the rate of observed to expected incidence was 1.0; i.e., no excess cancers were diagnosed.

Growth rates.—Growth rates could be calculated for 16 of

TABLE 8.—*Mean incidence test for overdiagnosis for the 6.25-year period A, March 1974 to June 1980; expected age-adjusted standardized incidence for Sweden 1974; mean study population defined in 1977; Swedish ST*[a]

21 carcinomas at the second screening, for 18 of 21 carcinomas at the third screening, and for 12 of 16 interval cases. The rates varied from a volume doubling time of less than 1 month to 13 months. Arbitrarily, the tumors were divided into 3 groups: "fast," "medium," and "slow" in regard to growth rate (table 10). Of the cancers detected at screening, 71% were medium types and 9% were fast, whereas of the interval cases 41% were fast and 34% were slow.

DISCUSSION

Here, as in other reports (*2–4, 6, 7*), the single oblique view was used. This method is employed at four of (at the present) five Swedish breast screening centers. At the fifth center the oblique view is combined with a craniocaudad view for screening (*8*). No differences in pick-up rates or interval cancer rates have been observed between these two variants of single modality screening (*5*). The costs, however, increase by a total of at least 60% by the apparently unimportant addition of the second view (*9*). The sensitivity of single oblique-view mammography expressed as the efficiency index, which takes into account interval cancers found during year 1 after screening, is 93% (*10*). The sensitivity of three-view mammography at our hospital is 95%. It is improbable that two views would surpass that. Given the very substantial cost increase incurred by addition of the second view, the price for the doubtful marginal gain seems exorbitant.

Though the rate of cases referred from screening by single-view mammography in our project was never high—1.4% in the pilot study (*2*)—it was lower at the third screening, only 0.8%. The specificity at the first screening was 99.2% and at the third, 99.8%. The decreasing referral rate had several causes: mounting experience, decreasing cancer detection rates, and the facts that a number of benign lesions with doubtful mammographic appearance had been excised at the first screening and that base-line X-rays were available for comparison.

The PV for biopsy recommendations by mammography was very high (78%), meaning that very few "unnecessary" biopsies were performed. The low negative biopsy rate could theoretically mean that some cancers were missed. Such tumors always turn up as interval cancers, and we do not believe that our rate of such cancers is unduly high; on the contrary, we consider it satisfactorily low. PV rates from other sources tend to be much lower; for instance, Moskowitz and Fox (*11*) reported 12% and Rombach (*12*), 31%. The four Swedish screening centers, of which ours is one, were found to have very similar PV (61–66%) at initial screening (*5*). In the report on the Breast Cancer Detection Demonstration Projects, this important aspect of screening was not mentioned. Those PV rates were probably lower than ours. The interval cancer rates were higher (*13*). The wide span in reported PV rates may reflect either differences of quality (examination and interpretation) or attitude or a combination of the two. The quality aspect is obvious and should need no further analysis: Bad examinations by inexperienced or badly motivated people lead to higher rates of both false positives and false negatives. The attitude current in Sweden includes concern both about the integrity and well-being of the individual participants and the buildup of public good will for the future benefit of the screening. We believe that it is extremely important to make every effort to keep the number of false-positive cases at an absolute minimum, since the fear and anxiety the women concerned have to live with until a definite diagnosis is reached may be devastating. From a practical viewpoint it is also important to reduce the number of false positives, because high rates may adversely affect future participation.

The participation rates were good throughout the period

TABLE 10.—*Growth rates of carcinomas detected at screening or in intervals between screenings*

Growth type	Doubling time, mo	Detections		
		At screening (%)	In intervals (%)	Total (%)
Fast	0–2	3 (9)	5 (41)	8 (17)
Medium	2.1–5	24 (71)	3 (25)	27 (59)
Slow	5.1–13	7 (20)	4 (34)	11 (24)
Total		34 (100)	12 (100)	46 (100)

reported. In fact, to our knowledge none better have ever been reported from any screening program. No less than 96% of women 40–69 years old participated in at least one screening, showing that the concept of breast screening and the way it was done were acceptable, despite mammography and breast screening being given a less-than-benevolent coverage by the mass media during the first 2 or 3 years of the period.

The rate of noninvasive and invasive cancers, 10 mm and less, was 55% at the first screening and 67% at the third screening and totaled 59%. Detecting "early" cancers, one aim of breast screening, was achieved. Though the actual number of cancer cases is quite small for each age group, there is no doubt that the efficiency of the screening was lower in younger women, partly because of the inherent lower diagnostic accuracy of mammography in the denser breasts of younger women and also because of too-long screening intervals. These intervals were longer than intended, 3.4 and 2.7 years, whereas we would have preferred 2.5 years at the most. However, it is possible that different intervals should be chosen, e.g., 1.5 years for women below 55 years of age and 3 years for those over that age. We still do not believe that there is enough evidence for a final decision on the optimum interval time, which also must include cost-benefit calculations. In the end a decision will probably be based as much on political and economical arguments as on strictly medical ones.

The model for observing possible overdiagnosis is certainly based on limited material, and nothing definite may be concluded from it. It could, however, be useful in ultimately proving or disproving our hypothesis that overdiagnosis could occur at a first screening only. Logically, it is probable that the tendency seen in the model will persist as the observation time increases. If that tendency turns out to represent a truth, we believe that this type of overdiagnosis may be an acceptable "cost," especially in view of the increasing use of very conservative treatment methods. The interpretation of the results is, however, complicated by earlier diagnosis (lead time) which will cause an age group shift. A cancer that should normally become clinically obvious for instance at age 72 years may well have its detection advanced to age 67 years because of screening. Thus some cases in lower age groups actually "belong" to the next older group.

The material on growth rates is small, at least concerning interval cancers. The rate of fast-growing cancers was higher among the interval cases, which could be expected, if one bears in mind length bias. There were also several slow-growing carcinomas, which represent observer interpretation errors at the screening examination.

Our opinion is that single oblique-view mammography, strictly monitored for high quality, has been proved to be very suitable for mass screening for breast cancer. It has a high sensitivity and specificity, is acceptable and reproducible, has a very high capacity, can be used in out-reaching mobile units, and is relatively cheap to implement. The most important issue, the impact of efficient breast screening by this method on breast cancer mortality, is at present under study in controlled, randomized trials in Sweden, with results forthcoming in 1 or 2 years.

Observer Variation in the Interpretation of Xeromammograms[1,2]

Norman F. Boyd,[3,4] Christina Wolfson,[5] Myron Moskowitz,[6] Thomas Carlile,[7] Michel Petitclerc,[8] Helen A. Ferri,[9] Eve Fishell,[10] Andre Gregoire,[11] Matthew Kiernan,[12] J. Donald Longley,[13] Imre S. Simor,[10] *and* **Anthony B. Miller[3]**

ABSTRACT—We have examined variation in the interpretation of xeromammograms among radiologists designated to take part in a Canadian multicenter randomized controlled trial of screening for breast cancer. Radiologists read 100 xeromammograms comprising 10 histologically proved cancers, 40 benign abnormalities, and 50 normal films. Radiologists' opinions differed widely on the frequency of suspected or identified cancer. The diagnostic category "suspicion of cancer" or "cancer" was selected by radiologists for 10–55% of the films, and biopsy or aspiration was recommended for 21 to 53% of patients whose films were examined. Agreement on specific diagnostic categories was greatest for the diagnosis of cancer; agreement was least for the diagnosis of benign abnormalities and intermediate for the diagnosis of normality. Known cancers were in general correctly identified. These results indicate a need for development of methods to reduce observer variation in the interpretation of xeromammograms while preserving diagnostic sensitivity and validity. Results also emphasize the importance of developing strategies to ensure quality control in multicenter trials.—JNCI 1982; 68:357–363.

Experienced radiologists may differ in their interpretation of radiographs, and the subject of observer variation in clinical radiology has received particular attention in connection with screening for pulmonary tuberculosis. Radiologists may fail to identify a substantial proportion of cases with roentgenographic evidence of tuberculosis and frequently change their readings on positive cases upon later rereading of the same films (*1–4*). These findings indicate the possibility that the detection of breast cancer by mammography might also be influenced by the observer who interprets the film.

While planning a multicenter randomized controlled trial of screening for breast cancer with mammography, we recognized that differences in mammogram interpretation between radiologists in the various centers could influence the number and stage of evolution of detected cancers and thus influence any effect of screening with mammography on breast cancer mortality. To determine the extent of differences between the diagnostic interpretations of mammograms and in the radiologists' recommendations for subsequent action, we conducted a study of observer variation in which all participating radiologists read the same set of mammograms.

MATERIALS AND METHODS

Xeromammograms and readers.—The xeromammograms were selected by two of us (M. M. and T. C.) from the files of two Breast Cancer Detection Demonstration Project screening centers. Fifty xeromammograms were selected from each center, and each set of 50 comprised 5 histologically proved cancers, 10 benign abnormalities confirmed by biopsy, 10 benign abnormalities not proved by biopsy, and 25 films that were regarded as normal. All "normal" films were of subjects who had been followed for at least 4 years after the film was taken and in whom breast cancer did not develop. No other criteria were established for the selection of films. One radiologist selected films thought to be representative of the three principal diagnostic classes; the other radiologist selected films from the Department's teaching file that for cancers showed only subtle radiologic features of the disease and for the benign abnormalities showed shared radiologic signs with the minimal breast cancers. The films from each subject comprised a mediolateral and craniocaudal view of each breast. All were regarded as technically satisfactory by the radiologist who selected them.

The set of 100 selected mammograms was copied by an industrial photographic process and arranged in random sequence. A complete set was sent to the two radiologists who had submitted films and to the other seven radiologists who had agreed to participate in a Canadian multicenter randomized controlled trial of breast cancer screening. All radiologists were members of university departments and had a special interest in mammography. The composition of the set of xeromammograms was known only to the two radiologists who provided the films. The technical quality of the reproduced films was assessed, in the absence of established physical methods of comparison, by the radiologists who submitted the original films. Some degradation of the image was thought to have occurred in the process of copying, but the copied images were considered adequate for diagnostic purposes. In the copying process the color of the background was changed from blue in the original to black in the copy. Each radiologist described each film, recorded a diagnosis, and made a recommendation for further action on a standardized precoded recording form.

Assessment of agreement.—The recording form listed 11 diagnostic categories that were condensed to 5 categories for the purposes of the analysis of agreement. These categories were: *a*) technically unsatisfactory film, *b*) normal breast, *c*) benign abnormality, *d*) suspicion of cancer, *e*) cancer present. As discussed below, films that were read as technically unsatisfactory were subsequently excluded for the purpose of analysis of agreement.

The readers recommended further therapeutic action for each patient by indicating if aspiration or biopsy should be performed, and if no immediate action was needed, when the next examination should be done. The recommendations made were then grouped into the following categories to assess agreement: *a*) aspiration and/or biopsy, *b*) reexamination in less than 6 months, *c*) reexamination in 6–12 months, *d*) reexamination in 12 months or more.

Statistical procedures.—Agreement on the use of the categories of diagnosis and recommendation was determined, after correction for expected chance agreement, with the use of the weighted kappa statistic (κ_w) (*5*) for each of the possible pairs of readers that could be formed from the participating radiologists. Weighted kappa was used because not all disagreements were considered to be of the same importance. For example, a disagreement in which a film was classified as normal by one radiologist and as benign by another was thought less serious than one in which a film was classified as normal by one reader and as cancerous by another. The weighted kappa statistic allows that not all disagreements are of equal importance and that some classes of disagreement, after adjustment with appropriate weights, can contribute to the overall level of agreement.

The weights used in calculating weighted kappa were those proposed for dichotomous ordinal scales by Cicchetti (*6*). (A dichotomous ordinal scale is one that is used to rate conditions that may be present or absent, and if present, that may exist in a number of states which can be ordinally ranked according to increasing levels of severity or seriousness.) With the weighted kappa statistic, a score of 1.0 indicates perfect agreement, and a score of zero indicates agreement that is not better than expected by chance. An example of the application of weighted kappa to the data presented here is given in the "Appendix."

For the analysis of agreement on diagnosis, with the weighted kappa, the scale comprised the diagnostic categories listed above after exclusion of the category of technically unsatisfactory. This exclusion was made because judgments about the technical merit of a film were thought to differ qualitatively from judgments about the diagnostic information that the film contained, and opinions about the technical merit of the film could not be ordinally ranked with diagnostic interpretations. One reader (radiologist G), who regarded 18 films as technically unsatisfactory, was excluded from the analysis of agreement on diagnosis, and any film regarded as technically unsatisfactory by any of the remaining readers was also excluded. The composition of the set of 85 films remaining after these exclusions is described in table 1.

TABLE 1.—*Composition of sets of films used for the analysis of agreement*[a]

Diagnostic category	Original set No.	Analysis of diagnosis No.	Analysis of recommendation No.
Cancer	10	10	9
Benign disease	40	33	27
Normal	50	42	25
Total	100	85	61

[a] *See test for reasons for exclusion.*

TABLE 2.—*Diagnostic classification of 100 films according to radiologist*

Diagnostic category	Diagnostic film classification according to radiologist								
	A	B	C	D	E	F	G	H	I
Technically unsatisfactory film	0	0	1	0	2	8	18	5	2
Normal	37	32	24	59	27	9	4	9	14
Benign disease	29	49	41	16	61	36	54	31	58
Suspicion of cancer	33	16	32	23	10	42	23	45	24
Cancer	1	3	2	2	0	5	1	10	2
Total	100	100	100	100	100	100	100	100	100

For the analysis of agreement on recommendations, with the weighted kappa statistic, the scale comprised the four categories listed above, and an additional category of films on which the radiologist had been unable to make a recommendation. The usual reason cited for not making a recommendation was that additional information, such as the patient's age or the findings of physical examination, was required. One reader (radiologist E), who was unable to make a recommendation on 32 films, was excluded from the analysis of agreement on recommendation, and any film on which any of the remaining readers could not make a recommendation was also excluded. The composition of the set of 61 films remaining after these exclusions is described in table 1.

In addition to overall agreement on the use of the four categories of diagnosis and recommendation, agreement on the use of each individual category was calculated (specific category agreement) to determine if there were particular categories that could not be reliably distinguished. Specific category agreement was calculated for each of the pairs of radiologists, and an example of the calculation is given in the "Appendix."

RESULTS

Diagnosis

Table 2 shows the frequency with which each radiologist used the four diagnostic categories and identified films as technically unsatisfactory. Use of the category "normal breast" varied from 4 to 59% according to reader, and between 16 and 61% of the films were read as showing a benign abnormality. The number of films suspected of containing cancer varied from 10 to 45%, and the number of films in which cancer was thought definitely to be present varied from 0 to 10%. Between 0 and 18% of the films were regarded as technically unsatisfactory according to the radiologists. Reader G, who classified 18 of the films as technically unsatisfactory, was excluded from the analysis of agreement on diagnosis shown in table 3. The radiologists who selected the films for this study are identified as readers A and B in the results that follow.

Table 3 shows the weighted kappa scores for agreement between all 28 possible pairings of these radiologists (excluding radiologist G) on the classification of the films. This analysis is confined to the 85 films that all of the remaining 8 readers agreed were technically satisfactory. All values of kappa indicated that agreement was significantly greater than expected chance agreement. The lowest value for κ_w was 0.23 between readers D and H, and the highest value was 0.59 between readers A and B. Five of the 28 values of kappa were less than 0.30, and only 4 were greater than 0.50.

Table 4 shows the mean kappa scores for agreement between radiologists (again excluding reader G) on the use of each individual diagnostic category. The scores cited for each radiologist are mean values for agreement between that reader and all other readers in the study on the use of each diagnostic group. (An example is worked out in the "Appendix" to illustrate how specific category agreement was determined.) Agreement was greatest on the category "cancer" with mean kappa values of 0.50 or more for all readers but one. Agreement was least on the category "benign abnormality" for all radiologists. Agreement on the categories "normal breast" and "suspicion of cancer" was intermediate.

To assess the possible influence on the results of excluding radiologist G, we repeated the analyses shown in tables 3 and 4 but limited them to the 71 films that all nine radiologists agreed were technically satisfactory. The results obtained were very similar to those shown in tables 3 and 4 and did not alter the conclusions drawn from those tables.

All 10 films known to contain histologically verified carcinoma of the breast were included in the set of films used for the analysis of agreement, and four were identified by all eight radiologists as cancerous or suspicion of cancer. Four of the eight readers identified all 10 films as cancerous or suspicion of cancer.

Recommendations for Therapy

Table 5 shows the frequency with which each radiologist used the four categories of recommendation or did not make a recommendation. Aspiration and/or biopsy was recommended for 21–53% of these cases according to the reader, and re-examination in 12 months or more was recommended in 30–60% of instances. The recommendation for reexamination in less than 6 months was not used at all by some radiologists and in as many as 20% of instances by others. The recommendation for reexamination in 6–12 months was also used quite variably. Radiologist E did not make a recommendation regarding 32% of the films and was excluded from the analyses of agreement that are shown in tables 6 and 7.

Table 6 shows the weighted kappa scores for agreement between radiologists on the use of these categories of therapy recommendation for the 61 films on which all remaining readers made a recommendation. All but one of the values for kappa differed significantly from expected chance agreement, and the highest value was 0.63. Of the 10 kappa values, eight were 0.50 or more, and two values were less than 0.30.

Table 7 shows the mean kappa scores for agreement between radiologists on the use of each category of recommendation. Agreement was greatest on the recommendation for aspiration and/or biopsy or for follow-up in a year or more. Substantially lower levels of agreement were seen for

TABLE 7.—*Mean kappa scores for agreement on the use of specific categories of recommendation*

Recommendation	Mean kappa scores according to radiologist							
	A	B	C	D	F	G	H	I
Follow-up in ≥12 mo	0.51	0.54	0.38	0.50	0.54	0.51	0.39	0.48
Follow-up in 6–12 mo	0.07	0.08	0.14	0.12	0.20	0.04	0.12	0.01

Aspiration and/or biopsy	0.58	0.58	0.44	0.54	0.51	0.63	0.48	0.54

all readers on both categories of recommendation for reexamination in less than a year.

We performed two additional analyses to assess the influence of exclusion on the results shown in tables 6 and 7. In the first, radiologist E was included, but the analysis was confined to the 47 films on which all radiologists made a recommendation. In the second, radiologists E, C, F, and G, all of whom did not make a recommendation for several films, were omitted, and the analysis was performed on the 97 films on which the remaining 5 radiologists did make a recommendation. Both analyses gave results that were very similar to those shown in tables 6 and 7.

Table 8 shows the number of radiologists who recommended biopsy according to the original diagnostic classification of the films. Three of the 10 films known to contain histologically verified breast cancer were recommended for aspiration or biopsy by all nine readers, eight of the 10 were recommended for biopsy by seven readers, and all 10 cases were recommended for biopsy or aspiration by at least five readers. Two of the films from breast cancer patients that were not recommended for biopsy by all readers appeared to give rise to particular difficulty. Both had been submitted by the radiologist who selected films showing only subtle radiologic signs of cancer. For one case of the five so selected, four radiologists did not recommend biopsy, and one radiologist did not make a recommendation. For another patient's film, three radiologists did not recommend biopsy. In 2 other patient's films submitted by this radiologist, one reader did not recommend biopsy. There were three films of cases submitted by the other radiologist for which one reader did not recommend biopsy and one for which no recommendation was made.

Of the 50 films from normal subjects, 14 were recommended for biopsy or aspiration by at least one reader, but there was little agreement on the recommendation for biopsy. In only three instances did three or more readers agree on the recommendation for biopsy or aspiration. Agreement on the need for aspiration and/or biopsy on films from patients thought to have benign breast disease was less than that for the known cancers, but it was greater than that for the known normal subjects.

DISCUSSION

As with other studies of observer variation, it should not be assumed without further evidence that these results apply to other radiologists or to other sets of xeromammograms. However, these results show that the radiologists who took part in this study varied greatly both in their diagnostic interpretation of xeromammograms and in their recommendations for further action. Although observer variation has been encountered in many radiologic prrocedures, it is likely to be particularly important in mammography. The concept of screening for breast cancer with mammography is based on the premise that radiologic signs suggesting the presence of cancer may be detected before other abnormalities, such as a palpable mass, are present. The performance of biopsy in response to the detection of such radiologic signs is expected to advance the time at which the diagnosis of breast cancer is made in an affected individual and so to increase the proportion of cancers found at a curable stage of their evolution (*7*). It can be expected, therefore, that in the context of screening for breast cancer with mammography, advice that a biopsy should be performed will often be based on the appearance of the mammogram alone and given in the absence of other evidence of breast disease that might help in making a clinical decision. Our results show that the advice to perform a biopsy based on the reading of a particular film may vary greatly from one radiologist to another. The known cancers included in the set of mammograms used in this study were, however, generally recommended for biopsy, and the analysis of specific category agreement showed that agreement on the presence of cancer was consistently higher than that for any of the other diagnostic categories. However, since the number of known cancers included in this set of films was small, it is unlikely that they included the full spectrum of radiologic signs of cancer. Therefore, no general conclusion regarding the diagnostic accuracy of mammography with respect to breast cancer should be drawn.

The principal sources of observer variation in this study were the diagnostic readings and therapy recommendations made about films from patients who did not have breast cancer. Whereas the actual prevalence of cancer in this set of mammograms was 10 of 85 (12%), the reported prevalence

TABLE 8.—*Agreement on the recommendation for biopsy according to diagnosis*[a]

Diagnostic category	No. of films	Agreement among following No. of radiologists recommending biopsy								
		9	8	7	6	5	4	3	2	1
Cancer	10	3	7	8	9	10	10	10	10	10
Benign disease, biopsy	20	1	7	10	13	14	17	18	19	19
Benign disease, no biopsy	20	2	2	5	6	7	9	9	12	18
Normal	50	0	0	0	1	1	2	3	6	14

[a] The rows of this table show, for each diagnostic category, the number of films recommended for biopsy and the number of radiologists recommending biopsy. Thus in the first row, of the 10 films from patients with cancer, 3 were recommended for biopsy by 9 readers, 7 by 8 readers, 8 by 7 readers, and so on.

of mammograms suspected of containing cancer varied from 10 to 55% according to the reader; there was also great variation in the frequency with which aspiration or biopsy was recommended. This problem is magnified by the composition of the set of films that we assembled and in particular by the inclusion of a relatively large number of films from patients with benign breast disease who had previously been judged to require biopsy. While such patients can be expected to have radiologic signs that cannot be reliably distinguished from cancer, it is clear from our results that radiologists may differ widely in their interpretation of these signs. As a result, as many as six of the 50 films from normal subjects were recommended for biopsy by at least one radiologist. This finding may arise in part from diagnostic habits formed in clinical practice, where there is a high prevalence of cancer in the films examined, and particular importance is placed on the need to avoid missing patients with breast cancer. Another contributing factor to this finding may be that radiologists were influenced by the circumstances of studying observer variation. Variability in the classification of patients who do not have breast cancer, however, is likely to have particularly important consequences in screening, where the prevalence of breast cancer is likely to be low, and the great majority of the women examined are free of breast cancer.

The results presented suggest some methods by which observer variation might be reduced. The analysis of specific category agreement on diagnosis showed that agreement on the category "benign abnormality" was so poor for all readers that it might be advantageous to eliminate this category. At least in context of screening for breast cancer, a diagnostic classification that seeks only to distinguish from all others those patients in whom cancer is present or suspected might be simpler to use and less subject to variability. Similarly, agreement on the recommendation to reexamine in less than 12 months was so poor that future studies might limit recommendations to the two categories of immediate aspiration and/or biopsy and follow-up in 12 months or more.

In addition to simplifying the classification of diagnosis and recommendation, explicit criteria for the recognition of those mammographic appearances that are most likely to be associated with invasive breast cancer, minimal breast cancer, and benign proliferative disorders need to be developed and tested. These criteria should, however, be based on mammographic signs that can themselves be reliably identified. Analysis of agreement on the mammographic signs recorded in this study showed that agreement on the presence or absence of architectural distortion, radiologic evidence of a breast mass, or of calcification, was less than that achieved for diagnosis. Thus for these readers none of the mammographic features recorded in this study offered a suitable basis for the formulation of criteria. Other methods of describing the observed information in a more reliable way need to be sought.

A further procedure whose feasibility and effects on observer variation merit study is that of dual reading of mammograms by two radiologists. When the dual reading of chest radiographs was introduced to screening for pulmonary tuberculosis, fewer films with radiologic evidence of active disease were missed (*8, 9*). In the present study the number of films available for the analysis for agreement on recommendation according to each of the four major diagnostic categories is small and any conclusions must be tentative. However, it appears that most readers were in agreement on the need for biopsy in those films that were subsequently shown to contain breast cancer, while there was less agreement about the need for biopsy when films in the other diagnostic categories were read. It is possible, therefore, that dual reading may reduce the effects of observer variation in the interpretation of xeromammograms and help to ensure that the greatest possible number of breast cancers are detected while minimizing the number of breast biopsies performed on women who do not have breast cancer.

APPENDIX

The example given here is intended to illustrate the way in which the results were calculated. More mathematical discussions of these indices of agreement may be found elsewhere (*5, 6, 10*) as may more detailed discussions written for clinicians (*11*).

Appendix table 1 shows the way in which radiologists A and B classified the 85 mammograms regarded as technically satisfactory according to diagnosis. Perfect agreement occurs in the cells of the table where both readers assigned the same diagnosis and the cells in which there is perfect agreement lie along the diagonal from the top left cell to the bottom right cell.

Calculation of Agreement and Weighted Agreement (PO_w)

The simplest method of calculating agreement is to add the number of films classified in each of the four cells in appendix table 1 that lie on the diagonal indicating perfect agreement and to divide this number by the total number of films classified. Thus the proportion of perfect agreement was: (21+17+15+1)/85=54/85=0.64.

This method of calculation regards all disagreements as being of equal importance. However, we may regard disagreements between suspicion of cancer and cancer or between normal and benign as being of little importance; we

APPENDIX TABLE 1.—*Diagnostic classification of films according to radiologists A and B*

	Diagnostic film classification according to:[a]				
	Radiologist B				
Radiologist A	Normal	Benign disease	Suspicion of cancer	Cancer	Total
Normal	21(1.00)	12(0.60)	0(0.20)	0(0.00)	33
Benign disease	4(0.60)	17(1.00)	1(0.80)	0(0.40)	22
Suspicion of cancer	3(0.20)	9(0.80)	15(1.00)	2(0.80)	29
Cancer	0(0.00)	0(0.40)	0(0.80)	1(1.00)	1
Total	28	38	16	3	85

[a] No. of films (cell weights in parentheses throughout).

may regard disagreements between normal and cancer as being of greater importance. To allow for differences in the importance of some categories of disagreement, we may "weight" disagreements differently. The weights used in this process are shown *in parentheses* in appendix table 1 and are proposed by Cicchetti (*6*).

Weighted agreement is calculated by multiplying the number in each cell by its associated weight and adding the products for the entire table. This sum is then divided by the total number of films classified. Thus weighted agreement in appendix table 1 becomes: $[(21\times1)+(12\times0.60)+(0\times0.20)+(4\times0.60)+(17\times1.0)+(1\times0.80)+(0\times0.40)+(3\times0.20)+(9\times0.80)+(15\times1.0)+(2\times0.80)+(0\times0.40)+(0\times0.80)+(1\times1.0)]/85=0.8682$.

Calculation of Weighted Agreement Expected by Chance (PC_w)

The calculation of agreement that was performed in the previous section did not take into account the amount of agreement expected by chance. To do this, an expected value is calculated for each cell. This is done by multiplying the row totals (that is, the cassifications of radiologist A) by the column totals (the classifications of radiologist B) and dividing by the grand total. Thus, for the top left cell of appendix table 1 the expected number is derived by: $(28\times33)/85=10.87$.

After an expected number has been calculated for each of the 16 cells of appendix table 1, expected agreement is determined by multiplying the expected number in each cell by the cell weight, in an identical manner to that used when weighted observed agreement was calculated, and then adding up the products. For appendix table 1: $PC_w=\{(10.87\times1.0)+(14.75\times0.60)+(6.21\times0.20)+(7.25\times0.60)+(9.84\times1.0)+(4.14\times0.80)+(0.78\times0.40)+(9.55\times0.20)+(12.96\times0.80)+(5.46\times1.0)+(1.02\times0.80)+(0.45\times0.40)+(0.19\times0.80)+(0.04\times1.0)\}/85=0.6788$.

Calculation of Weighted Kappa (κ_w)

As shown above, some agreement on the diagnostic classification of films can be expected by chance alone. The kappa statistic corrects the amount of agreement observed for the agreement that is expected by chance. It is preferred to other indices of association, such as the correlation coefficient, because it expresses the extent to which two sets of observations agree, and not merely the extent to which they are related (*11*). Weighted kappa is calculated by the formula: $PO_w-PC_w/1-PC_w$, where PO_w is the proportion of weighted agreement, calculated as in the first section above, and PC_w is the proportion of weighted agreement expected by chance, calculated as in the second section above. For the example shown in appendix table 1, $\kappa_w=(0.8682-0.6788)/(1-0.6788)=0.5898$.

Kappa will have the value 0 if agreement observed is equal to agreement expected by chance ($PO_w=PC_w$); kappa will be +1 if observed agreement is perfect ($PO_w=1.0$). Kappa will be less than 0 if observed agreement is less than agreement expected by chance.

Calculation of Specific Category Agreement

Calculation of kappa values for agreement in specific categories also required calculation of the amount of agreement observed for a specific category (*SO*), the amount of agreement expected by chance for that category (*SC*), and correction of the agreement observed for the agreement expected by chance (kappa).

The amount of specific category agreement observed (*SO*) is calculated from the number of agreed upon cases in a particular diagnostic category, divided by the average number of cases to which that diagnostic category is applied. For example, in appendix table 1 radiologists A and B agreed that 21 films were normal. The category ""normal" was applied to 33 films by reader A and to 28 films by reader B. The average frequency to which the category was applied is then $33+28/2=30.5$. Observed specific category agreement is thus $21/30.5=0.69$.

With the use of cell weights, calculation of specific category agreement was expanded to take into account partial disagreements in an analogous manner to that described in the first section of this appendix.

The amount of specific category agreement expected by chance (*SC*) was calculated for each cell and each pair of readers by first determining the expected number for the cell. This was done by multiplying the number of films placed in that category by one reader by the number placed in the category by the other reader and then dividing the product by the total number of films. The amount of specific category agreement expected by chance is then obtained by dividing the expected cell number by the average frequency with which the two readers used the category. Thus for the category "normal" in appendix table 1, the expected number of films in the cell is $(33\times28)/85=10.87$. Expected specific category agreement on the category "normal" is then $10.87/30.5=0.36$.

Finally, the chance corrected specific category agreement (Kappa) for any given nominal category is given by: kappa$=(SO-SC)/(1-SC)$. In the example considered above for the category "normal", and not taking into account weights for partial agreement, kappa$=(0.69-0.36)/(1-0.36)=0.52$.

The assessment of specific category agreement is fully discussed by Cicchetti et al. (*10*).

Multiple Cell Lines From Patients With Malignant Melanoma: Morphology, Karyology, and Biochemical Analysis[1,2,3]

Toni U. Semple,[4] George E. Moore,[4] Robert T. Morgan,[4] Linda K. Woods,[4] *and* Laurie A. Quinn[4,5]

ABSTRACT—Of 23 cell lines representing 8 patients with malignant melanoma, one cell line from each patient has been extensively characterized by means of phase morphology, ultrastructural morphology, biochemical markers, steroid receptor protein analysis, and steroid hormone production. Extensive cytogenetic characterization was compiled from seven of the eight cell lines. The melanocytic derivation of the tumor cell lines was supported by the detection of the catecholamines epinephrine, norepinephrine, and dopamine. In addition, well-defined melanosomes were present in six of the seven lines whose ultrastructures were examined morphologically. None of the lines produced α-fetoprotein, β-human chorionic gonadotropin, or carcinoembryonic antigen in detectable amounts. The individuality of the cell lines was confirmed by phenotypic patterns of isozymes and by karyology.—JNCI 1982; 68:365–380.

Mammalian cells established as permanent lines in vitro are increasingly useful in many areas of scientific pursuit not previously associated with tissue culture. Normal and abnormal substances produced eutopically or ectopically by cells in culture are a valuable resource. The effects of various hormones, nutrients, and growth factors on the metabolism and survival of mammalian cells can be assayed in vitro. Cell lines established from different types of cancers can be used by the oncologist to identify and categorize clinically significant patterns of biological aberrations in neoplastic disease.

It is imperative that every cell line used for in vitro studies be characterized as fully as possible. The array of attributes so delineated allows investigators interested in a particular attribute to select a cell line for use without preliminary screening of many cell lines. More importantly, the characteristics described provide for periodic reidentification of each cell line.

We have almost 40% success in establishing continuous cell lines from patients with malignant melanoma. Malignant melanoma cell lines are common; multiple cell lines from a [illegible] are less common. Very few malignant [illegible] [illegible] literature have been thoroughly [illegible]. We [illegible] of 23 cell lines from 8 patients [illegible] malignant melanoma.

MATERIALS AND METHODS

Case histories.—Patient A (COLO 297 cell line): On September 2, 1976, a [illegible] removed from a 76-year-old white [illegible] and cultured. The pathologic diagnosis was malignant melanoma with sheets of heavily pigmented pleomorphic cells.

Patient B (COLO 296, COLO 298, COLO 300, and COLO 302 cell lines): On October 5, 1976, a 47-year-old white woman was seen with a 6-cm mass in the inguinal area, subsequent to the excision of a malignant melanoma from the leg that was done elsewhere. The tissue excised by groin dissection was confirmed as a pigmented malignant melanoma. The metastatic tumor tissue was cultured by our laboratories. The patient is alive and well.

Patient C (COLO 322 and COLO 324 cell lines): A 42-year-old white male had a black spot removed from his cheek by dermabrasion, but local regrowth and probable metastases were noted. Following chemotherapy, a neck dissection and subsequently an axillary dissection were performed in October 1975. Tissue culture from the regional lymph nodes contained malignant melanoma cells with pleomorphic forms, prominent nucleoli, and some bizarre mitoses. This metastatic tumor tissue was cultured.

Patient D (COLO 342, COLO 343, and COLO 349 cell lines): This 69-year-old white male had undergone excision of a malignant melanoma from the arm and the axillary nodes some years ago. A melanotic metastasis in a groin lymph node was excised in January 1978 and cultured.

Patient E (COLO 358, COLA 361, COLO 362, and COLO 363 cell lines): On September 7, 1971, a 63-year-old white male patient was admitted with axillary and cervical metastases 7 years after excision of a malignant melanoma of the skin over the left scapula. The diagnosis was confirmed and the tumor tissue was cultured. The patient was given chemotherapy and is well.

Patient F (COLO 368 and COLO 381 cell lines): A right axillary mass was excised in July 1977, 6 months after a bleeding mole had been removed by cautery from the back of this 35-year-old white male; local recurrence was also present. A third metastasis in the right flank was excised, confirmed as a pigmented malignant melanoma, and cultured. Despite chemotherapy, the patient died in a few months.

Patient G (COLO 383 and COLO 415 cell lines): On November 15, 1978, a large neck mass was excised from a 21-year-old white woman 2 years after a lightly pigmented malignant melanoma was removed from her back. A pathologic diagnosis of amelanotic melanoma was made and

tissue sent to our cell culture laboratory. Both this patient and her father died of malignant melanoma.

Patient H (COLO 417, COLO 419, COLO 437, COLO 441v, and COLO 442v cell lines): In July 1979 a 30-year-old white male with schizophrenia was noted to have developed a huge axillary mass that an examination proved to be a pigmented malignant melanoma. This tissue was cultured. The patient died 1 year later from extensive disease.

Cell culture.—Our methods for tumor cell cultures have been described (*1*). Tumor specimens were finely minced in RPMI-1640 medium (Irvine Scientific, Irvine, Calif.) with 20% FBS (heat inactivated at 56°C for 30 min), and 0.25 ml of the resultant cell suspension was pipetted in 4-ounce flint-glass bottles. No more than 1 ml of a selected medium was added to each flask. The flasks were loosely capped and placed in a humidified 37°C incubator containing 10% CO_2 in air for 24–48 hours. Each week, or as needed, 1–5 ml of appropriate medium was added to the culture until growth stabilized. We made subcultures either by sharply rapping the flask on the palm of the hand to loosen cells or by using a rubber scraper and then pouring suspended cells into another flask.

The lymphoid cell lines were established by methods previously described (*2*).

Representative cell lines were selected for extensive characterization.

Morphology.—Morphologic studies were accomplished by the examination with phase optics of Leighton tube subcultures of the cell lines. Duplicate cover slips were fixed for 3 minutes in absolute ethanol, stained with May-Grünwald-Giemsa, and mounted for permanent records.

For the study of the ultrastructural morphology, cells were harvested, pelleted, and fixed in 4% glutaraldehyde in 0.1 *M* phosphate buffer (pH 7.3). The methodology for embedding and staining has been reported elsewhere (*3*).

Chromosome analyses.—Chromosome preparations for each line analyzed were made according to techniques described previously (*4*). Slides were also stained conventionally with Giemsa to determine the presence of DM chromosomes (small, acentric chromosomes). Chromosome mode was determined by direct microscopic observation of 50 cells at metaphase. We selected 8–14 metaphase plates to be photographed and karyotyped.

Pigment formation.—For enhancement of pigment formation, cells were grown for 2 weeks in GEM 1717 media (Irvine Scientific) with 10% FBS containing 0.44 m*M* L-tyrosine and pelleted into round-bottomed test tubes. The resultant pellet was allowed to stand in the light for 2 weeks. The color of the pellet was then compared visually to that of control pellets treated in the identical manner except for the additional tyrosine.

CEA.—CEA levels were determined with a radioimmunoassay technique available in kit form by Roche Diagnostics, Nutley, N.J. Preparation of cultures for this assay has been described previously (*5*).

Isozyme phenotypic patterns.—Phenotypic isozyme analyses were performed in accord with the starch-gel electrophoretic methods of Harris and Hopkinson (*6*). Glucose-6-phosphate dehydrogenase mobility was determined with the use of the standard clinical procedure of Helena Laboratories, Beaumont, Tex. For sample preparation, 10^6 cells were freeze-thawed three times in 0.1 ml deionized water.

Plating efficiency.—For each cell line, 3×10^2 or 6×10^2 cells were plated in each of three 35-mm tissue culture dishes; 1.2 ml of RPMI-1640 plus 20% FBS was the final volume in the plates. The plates were placed undisturbed for 7 days in a humidified 37°C incubator containing 10% CO_2. After the incubation period, the medium was aspirated from the plates, and cell colonies were fixed with methanol–acetic acid (3:1) and stained with Gram's crystal violet. The plating efficiency was calculated by: (Average number of colonies/number of cells originally seeded)×100=plating efficiency.

Ectopic elaboration of cell products.—β-HCG and AFP determinations were performed by Immunological Associates of Denver, Denver, Colo. Calcitonin, serotonin, and the fractionated catecholamines were determined by UpJohn Laboratories, Woodland Hills, Calif., and Kalamazoo, Mich. In all cases, aliquots from 15 ml of spent medium from cultures not fed for the preceding 48 hours and containing 1.5×10^6 cells were used for the determinations. These determinations were all performed in 1980 on cultures in continuous culture since their establishment.

Production of steroid hormones.—Estrogen and progesterone production was determined by use of an Estrogen Pak (^{3}H-labeled estrogens, estradiol, and estrone; New England Nuclear Corp., Boston, Mass.) and a Progesterone Pak (^{3}H-labeled progesterone; New England Nuclear Corp.), respectively. Preparation of cultures for steroid hormone production assays has been described elsewhere (*7*).

Steroid receptor assays.—Assays of 4S and 8S receptor proteins were determined as previously described (*7*).

Mycoplasma.—We monitored mycoplasma contamination by staining cytocentrifuge preparations of the cells with Hoechst dye 33258 (bisbenzamide) according to the methods of Chen (*8*) or with DAPI by the method of T. E. Swanson (personal communication). Cell preparations were fixed in methanol–acetic acid (3:1) for 10 minutes, stained in 0.1 μl DAPI/ml for 5 minutes, leached in distilled water for 10 seconds, mounted in phosphate-buffered saline, and viewed with UV epi-illumination.

Storage in cell banks.—Cell lines were preserved in ampuls by the suspension of 10^6 cells/ml in RPMI-1640 medium plus 20% FBS, 12.5% dimethyl sulfoxide, and antibiotics and then slowly cooled to −80°C.

RESULTS

Cell culture.—The history of each cell line is presented in table 1. All cell lines were established from metastases.

Phase morphology.—All cell lines (with the exception of COLO 417) grew as spindle-shaped to triangular–dendritic and cuboidal cells. The percentage of each cell type varied among the different lines. Bizarre cells with extensive dendritic processes were observed in all the lines. When confluent, all lines formed clumps of viable cells that either loosely attached to the monolayer or floated free in the supernatant. COLO 417 was comprised primarily of round to oval cells that were loosely attached or grew in the supernatant. Spindle cells were occasionally observed, be-

[b] DTIC=imidazole carboximide.

coming more common with confluence. Giant cells with multiple nuclei were frequent in COLO 417.

Pigment granules were observed in all cell lines. The heaviest pigmentation was observed in COLO 297. Nuclei of the cells were round to ovoid with prominent nucleoli. Intracellular bridges were seen in COLO 361 and COLO 415. All the lines with the exception of COLO 361 grew rapidly and formed confluent monolayers in 4–5 days; COLO 361 formed a confluent monolayer in 2–3 weeks.

Section A of figures 1–8 show phase morphology for all lines described.

Ultrastructural morphology.—Electron photomicrographs revealed melanosomes that ranged from abundant and heavily pigmented in COLO 297 to rare and lightly pigmented or nonpigmented in COLO 417. COLO 415 did not have any ultrastructure clearly identifiable as that of a melanosome or premelanosome. All cells displayed endoplasmic reticulum in varying amounts, but the endoplasmic reticulum appeared abnormal in all cells. Unusual endoplasmic reticulum incorporated into circular patterns was observed in COLO 415. Polysomes were abundant in COLO 297, COLO 324, and COLO 417. Numerous, but aberrant mitochondria were observed in all lines. Well-formed Golgi structures were abundant. Lipid vacuoles and glycogen deposits were observed in all lines. Fenestrated nucleoli were apparent in all lines. Microvillar projections were seen only in COLO 349 and COLO 417, being most plentiful in COLO 417. Tight junctions are not expected in melanoma cell lines but were plentiful in COLO 417.

Sections B of figures 1–8 exemplifies the ultrastructural morphology of these lines. The ultrastructural morphology of COLO 361 is not available.

Chromosome analyses.—Due to a laboratory accident, one cell line (COLO 361) has been lost. Therefore, chromosome analysis of this line is not available. Early harvests of this line had structural and numerical chromosome abnormalities. Karyotypes for the other cell lines appear in figures 9–15. Major chromosome markers were defined as those appearing in 50% of the cells analyzed and were designated by "M." No marker chromosomes common to all cell lines were observed. Chromosomes 1, 3, 5, 6, and 7 were the most frequently involved, whereas chromosomes 2, 4, 9, 11, 15, 20, 21, 22, X, and Y were infrequently involved (table 2). The chromosome mode and range near the mode for the seven cell lines examined are listed in table 3. All lines exhibited chromosome numbers within the triploid or tetra-

[b] Bimodal.

ploid range. Four of the seven lines have sequential analysis data. Those lines showed no particular pattern of chromosome gain or loss. The percentage of cells with chromosome counts near the mode increased in three of four cases. No correlation was observed among patients' stage of disease, number of months until death, length of time of cell lines in culture, number of chromosome abnormalities, or cell line stability. Table 4 lists the marker and DM chromosome occurrence in the cell lines examined. The frequency of cells with DM varied from 4 to 50%.

Isozyme analyses.—Results of isozyme analyses are presented in table 5.

Pigment production and ectopic elaboration of cell products.—The results of enhanced pigment production and elaboration of cell products are presented in table 6.

Steroid receptors.—Steroid receptor analyses are presented in table 7. Of three biopsy specimens that expressed positive estrogen receptor proteins, only COLO 342 retained this characteristic in culture.

Steroid hormone production.—COLO 296, COLO 297, COLO 342, COLO 368, and COLO 381 were examined for hormone production; none were positive.

Plating efficiencies.—Plating efficiencies were as follows: COLO 297=12%, COLO 298=27%, COLO 349=26%, COLO 324 and COLO 417=19%, and COLO 381 and COLO 415=17%. These figures were obtained from plates containing 300 cells/dish. There was no statistically significant difference ($P>0.1$) in the plating efficiency in plates containing 600 cells/dish.

TABLE 4.—*Marker and DM chromosome occurrence in malignant melanoma cell lines*

Cell line	Mean No. of chromosomes per cell	Percent of marker contribution to chromosome No.	Percent of cells with DM
COLO 297	74	25	50.0
COLO 298	73	23	9.3
COLO 324	120	10	41.1
COLO 349	79	20	4.0
COLO 381	75	14	5.7
COLO 415	86	19	40.2
COLO 437	59	14	10.0

Mycoplasma.—Although rare, sparse mycoplasma contamination was seen in some lines; at no time were all cultures of these lines positive. Positive cultures were treated with Tylocine or tetracycline until all evidence of mycoplasma had been eliminated and the cultures remained free of contamination, or the positive cultures were discarded. All characterizations were performed on cultures free from mycoplasma.

DISCUSSION

To derive maximum benefit from cultured mammalian cells, investigators must be informed of cellular characteristics that satisfy their particular area of investigation. Additionally, for those investigators interested in the histogenesis of a particular type of cancer, evidence of the ascribed origin of the cells is important. Finally, characteristics fingerprinting a particular cell line are mandatory for the subsequent reidentification of that cell line. Cross-contamination is an increasingly common occurrence and is recognizable only when cell lines have had marker properties identified previously. The variety of markers presented in our report may be utilized to assess the potential value of these lines to investigators and to provide a means to identify the cell lines described.

We have characterized eight cell lines representative of 23 tumor cell lines established from 8 patients with malignant melanoma. Cell lines from 6 of our 8 patients are similar to each other with respect to morphology by phase optics, ultrastructural morphology, and growth characteristics. They also resemble melanoma cell lines previously described by us (*9*). Two cell lines, COLO 361 from patient E and COLO 415 from patient G, differ from most malignant melanoma cell lines established in our laboratory. For example, melanosomes were not observed in COLO 415, and addition of extra tyrosine failed to increase pigment production in either line. Although the morphology of the two lines was similar, their isozyme phenotypes were differ-

ent, indicating that they were distinct cell lines. The histopathology studies on both of these metastatic lesions did not reveal pigment in the cells. Both patients had "malignant melanoma" lesions removed previously from different sites. The possibility of the derivation of these cell lines from secondary primary lesions should be considered; however, there was no clinical evidence of other primary cancers in these patients. It is also possible that these two cell lines represent a population of melanoma cells that does not usually survive culture, is primitive and/or undifferentiated, and does not generate melanosomes.

Occurrence of aberrant karyotypes was expected in the malignant cell lines. All human tumor cell lines established in this laboratory (>165 different lines) exhibit abnormal chromosome constitutions. All of the lines derived from different individuals can be distinguished on the basis of karyotype. The extensive analyses that were possible through the use of cultured cells did not reveal specific chromosome breakpoints in common markers. Such breakpoints would indicate that the observed chromosome abnormalities were related to the malignant melanoma disease process, as has been observed for some other types of cancers (*10–13*). In this case, however, the significance of chromosome aberrations remains speculative. The presence of DM is also expected. DM have been detected in all but one tumor cell line scanned for their presence by us. Theoretically, malignant melanomas are derived from neural-ectodermal tissue and might be expected to produce some of the products associated with amine precursor uptake and decarboxylase cells. The selection of biochemical markers was

made in part on this basis. The cell lines were assayed for the production of serotonin, calcitonin, and the catecholamines epinephrine, norepinephrine, and dopamine. The synthesis of the catecholamines from 3,4-dihydroxy-L-phenylalanine, a precursor to 5,6-indolequinone (the monomer of melanin pigments), might be expected of a melanocyte whose metabolic controls are abnormal. In addition, AFP and CEA assays were selected to demonstrate the possible dedifferentiation of the cells to a more embryonic stage of ontogeny. β-HCG was assayed and has been previously associated with melanoma cell lines (*14*).

All the cell lines tested produced significant levels of one or more of the catecholamines. Although there has recently been a report of melanoma producing serotonin in vivo (*15*), the failure of these cell lines to produce either serotonin or β-HCG may reflect the variable gene derepression which is perhaps associated with chromosome aberrations. Alternatively, the culture environment may have selected against those cells producing these substances. The lack of detectable CEA or AFP may simply indicate that there is still sufficient genetic control in these cell lines to prevent expression of the embryonic antigens.

The detection of estrogen receptors in three of six fresh tumor specimens is compatible with other reports (*16*). Only one cell line retained detectable levels of estrogen receptors. Three of eight had glucocorticoid receptors, and one of eight had androgen receptors. Such cell lines should be valuable for studies of receptor activity. Selective pressures of the culture media with sera containing variable amounts of hormones probably influence survival of cells from the heterologous mosaic of mutant cells in the original tumor with or without hormone receptors.

This spectrum of melanoma cell lines is also valuable to investigators seeking a common specific melanoma antigen.

In summary, the individuality of eight human malignant melanoma cell lines has been established through phenotypic isozyme fingerprinting, karyotypes, and biochemical markers. The original histologic diagnosis of melanoma has been conclusively confirmed in six of these lines, but the characteristics of two cell lines are atypical and cause one to reconsider the nature of the tumor from which the lines were established. However, the biochemical data indicated that these lines are probably of malignant melanotic origin, despite the absence of melanin in subsequent metastases. In our opinion, there will always be primitive cancers derived from precursors of entities such as melanoma that may not contain type-specific structures, functions, cell products, biologic behavior, or antigens. These cancers will give question to the histogenesis, diagnosis, and therapy of the lesion.

Prolactin Receptors in Human Breast Tumors[1,2]

Lucile Turcot-Lemay[3,4,5] *and* **Paul A. Kelly**[3,6]

ABSTRACT—Prolactin-binding sites were determined in 759 human breast tumor biopsy specimens. Ovine prolactin (oPRL) was used in the binding assay of 569 tumors with 13% of the tumors showing a positive content with more than 1% specific binding. Human prolactin (hPRL) was utilized for 343 tumors with 38% of the tumors binding 1% or greater of the added radioactivity. When human growth hormone (hGH) was used as the labeled ligand in 95 tumors, only 2% of the tumors specifically bound more than 1% of the hGH. A total of 153 tumors were assayed simultaneously with the use of labeled hPRL and oPRL. Whereas 10.4% of the tumors showed the presence of prolactin-binding sites (>1% specific binding) when oPRL was used, an approximately threefold increase (29.4%) in tumors possessing prolactin receptors was revealed when hPRL was used as the labeled ligand. Therefore, hPRL is the preferred ligand for the assessment of prolactin receptor levels in human breast cancer biopsy specimens.—JNCI 1982; 68:381–383.

The measurement of hormone receptor levels for estrogen and progesterone in breast cancer biopsy specimens has become a routine procedure to establish the hormonal dependency of these tumors and to direct the type of therapy to be given to these patients (*1–3*). It has been demonstrated, however, that only 55–60% of the receptor-positive tumors respond to various forms of endocrine treatment, whereas less than 10% of the patients with receptor-negative tumors respond to such treatment (*1*, *4*, *5*). Therefore, something not predicted by assessment of steroid receptor levels might be involved in the growth and development of these tumors. Prolactin has a well-established role in the development and growth of experimental rat and mouse mammary tumors (*6–9*), and prolactin receptors have been identified in these tumors as well as more recently in human breast tumors (*10–14*).

During the last 2 years, we have assayed prolactin receptors in 759 human breast tumors sent to our laboratory by the surrounding medical centers for steroid receptor determination. A comparison of the optimum type of labeled ligand to use in the assay of prolactin receptors in breast tumor biopsies was done.

MATERIALS AND METHODS

Membrane preparation.—Human breast tumor specimens or biopsy specimens were received for 17β-estradiol and progesterone receptor assays from several regional hospitals and were frozen on Dry Ice or in liquid nitrogen. Tumors were first pulverized, then homogenized with 2- to 10-second bursts of a Polytron PT-10 homogenizer in 25 m*M* Tris–HCl (pH 7.4), 1.5 m*M* EDTA, 10 m*M* thioglycerol, and 10% glycerol, and finally centrifuged at 13,000×*g* for 15 minutes. The supernatant was centrifuged at 105,000×*g* for 90 minutes. The resulting cytosol was used for the steroid receptor-binding assays. The crude microsomal pellet was resuspended in 25 m*M* Tris–HCl and 10 m*M* $MgCl_2$ (pH 7.4) with a Teflon–glass homogenizer, and the protein concentration was measured (*15*) with bovine serum albumin as standard.

Hormones.—oPRL (NIH-P-S12; 35 IU/mg) and hGH (HS-2160E; 1.7 IU/mg) were gifts of the National Pituitary Agency, University of Maryland School of Medicine, Baltimore, Md. and by the National Institute of Arthritis, Metabolism, and Digestive Disease, National Institute of Health. The hPRL for iodination was provided by Dr. Henry Friesen, University of Manitoba, Winnipeg, Manitoba.

[^{125}I]oPRL-, [^{125}I]hPRL-, and [^{125}I]hGH-binding assays.—The oPRL, hPRL, and hGH (5 μg each) were iodinated with low concentrations of chloramine-T (500 ng). The specific activities varied from 35 to 65 μCi/μg for oPRL and from 72 to 75 μCi/μg for hPRL and was 36.4 μCi/μg for hGH, as calculated by isotope recovery.

Approximately 100,000 cpm of [^{125}I]oPRL, [^{125}I]hPRL, or [^{125}I]hGH was incubated with 300 μg of tumor membrane protein in a final volume of 0.5 ml in 25 m*M* Tris–HCl and 10 m*M* $MgCl_2$ (pH 7.4) containing 0.1% bovine serum albumin. The incubation was performed at 23°C in the presence or absence of an excess of unlabeled oPRL for 16–20 hours. The incubation was stopped by addition of 3 ml of the incubation buffer. Bound and free hormones were separated by low-speed centrifugation (2,000×*g*) at 4°C for 15 minutes. After decantation, the pellets were counted in an LKB gamma spectrometer. Specific binding was obtained by subtraction of nonspecific from total bound radioactivity. This value was expressed as percentage of the total radioactivity added to the tube (*7*). Nonspecific binding ranged from 2 to 4% of the added radioactivity. We established a limit of sensitivity of 0.5% by obtaining a difference of at least 500 cpm between total counts and nonspecific counts for the biopsy samples. Differences of less than 500 cpm (corresponding to 0.5% of the 100,000 cpm of added radioactivity) were considered below the limit of sensitivity for the technique, on the basis of a combination of a number of factors routinely examined including counter background, homogeneity of labeled hormones from one iodi-

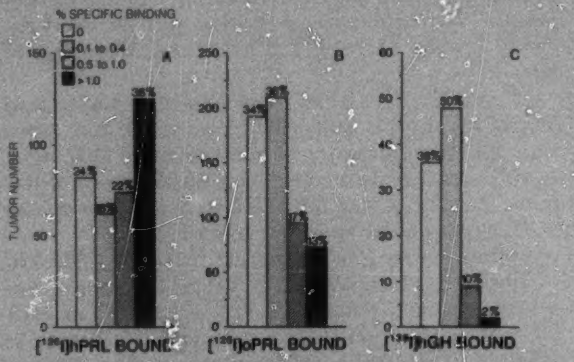
TABLE 1.—*Comparison of specific binding to 153 human breast cancer biopsy specimens with oPRL and hPRL as the labeled ligand*[a]

Ligand	Specific binding at binding values of:				
	0%	0.1–0.4%	0.5–0.9%	1.0–1.9%	>2.0%
[^{125}I]hPRL	25.5% (39)	18.3% (28)	26.8% (41)	20.3% (31)	9.1% (14)
				29.4%	
[^{125}I]oPRL	50.4% (77)	25.5% (39)	13.7% (21)	7.8% (12)	2.6% (4)
				10.4%	

[a] *Numbers in parentheses* indicate the numbers of tumors.



TEXT-FIGURE 1.—Comparison of specific binding of prolactin with [^{125}I]hPRL (A, 343 tumors), [^{125}I]oPRL (B, 569 tumors), and [^{125}I]hGH (C, 95 tumors). Binding values are arbitrarily divided into four categories (0, 0.1–0.4, 0.5–0.9, and 1.0% of the added radioactivity specifically bound).

nation to the next, nonspecific binding values, and degree of binding, which can be competed by an excess of unlabeled prolactin.

RESULTS

Text-figure 1 shows a comparison of prolactin-binding sites. Three different labeled ligands in human breast cancer biopsy samples were used. On the basis of the background sensitivity of the technique in our laboratory, values greater than 0.5% of the added radioactivity represented significant specific binding of prolactin. With [^{125}I]hPRL (text-fig. 1A), 58% of the biopsy specimens fell into this category compared to 30% with [^{125}I]oPRL (text-fig. 1B) and only 12% with [^{125}I]hGH (text-fig. 1C). When 1% or greater of the added radioactivity was used as the criterion for selecting tumors that showed positive prolactin binding, the values were 36, 17, and 2%, respectively, for hPRL, oPRL, and hGH. There were equally less tumors showing no measurable prolactin binding (0%) or borderline values (0.1–0.4%) when hPRL was used as the tracer.

Table 1 compares ^{125}I-labeled oPRL and hPRL binding to 153 human breast cancer biopsy specimens. Binding studies were done in parallel with both freshly iodinated hormones. Compared to the use of oPRL as tracer, the use of [^{125}I]hPRL as tracer allowed the detection of almost three times as many tumors possessing prolactin receptors (29.4 vs. 10.4%) and also resulted in a twofold increase in the tumors showing moderate binding values (0.5–0.9%). There was no correlation between the level of prolactin receptors and the concentration of receptors for either 17β-estradiol or progesterone in these tumors (data not shown).

DISCUSSION

Human breast tumors possess membrane prolactin-binding proteins in sufficient amounts to be detected when the appropriate procedure is used. Specific binding of 1% or greater of the added radioactivity has been considered positive (*10*). Di Carlo and Muccioli (*14*), using an assay similar to ours, found positive values for prolactin receptors in 32.5% of their tumors, which is very close to our value of 36%. The present studies indicate the importance of the use of hPRL rather than oPRL for the determination of prolactin receptors to human breast cancer biopsy specimens. A rather puzzling result was the low binding values found when hGH was used as a labeled ligand. We and others have reported that hGH effectively competes with [^{125}I]-oPRL or [^{125}I]hPRL in breast tumor samples (*9*, *14*). The restrictions involved in performing a study such as this limit the type of basic information that can be obtained therefrom. We were limited to using the homogenization buffers and techniques that are optimum for the determination of steroid receptor levels. Studies are in progress to investigate methods to increase prolactin binding by differential gradient centrifugation. Also, the use of [^{125}I]hGH will be compared more extensively with that of hPRL in the same tumor specimens, especially in view of the increased efficacy of labeled hGH binding to human mammary epithelial cells (Turcot-Lemay L, Kelly PA: Unpublished observations).

These studies confirm the existence of prolactin receptors in human breast cancer biopsy specimens. It will be important to investigate the possible therapeutic implications of the determination of prolactin receptor levels in the prediction of the response of breast cancer patients to endocrine therapy.

Tumor Promoter 12-*O*-Tetradecanoylphorbol 13-Acetate: Effect on Complement and Epstein-Barr Virus Receptors in Human Lymphoblastoid Cell Lines[1,2]

Naoki Yamamoto,[3] Takashi Mitsuma,[4,5] *and* Arnold Vogt[4,6,7]

ABSTRACT—The effect of the tumor promoter 12-*O*-tetradecanoylphorbol 13-acetate (TPA) on the C3 and Epstein-Barr virus (EBV) receptors in various human lymphoblastoid cells was investigated with the use of the erythrocyte-antibody-complement (EAC) rosette formation method and a quantitative bioassay for EBV receptors. TPA caused a significant decrease of C3 receptors in the cultures of both Raji and SB4 cells (by ≈50% of the C3 receptors in untreated cultures at 10 ng/ml). Kinetic studies revealed that the rate of reduction was rather moderate but progressive, reaching a maximum 5 days after treatment with TPA. Kinetic studies showed that EBV receptors also decreased, similar to the reduction seen with C3 receptors after TPA treatment. The effect of TPA on the reduction of C3 receptors was observed not only in these cells but also in other EBV-positive B-cells, subclones of SB4 cells, and MOLT-4 cells. However, in an EBV-negative B-cell line, BJAB, EAC rosette formation was significantly enhanced.—JNCI 1982; 68:385–390

It has been well established that initiators and promoters regulate the two-stage mouse skin carcinogenesis model (*1*). Most initiators generate elecrophilic metabolites that covalently bind to DNA. However, the promoters are thought to interact directly with the cells without requiring such metabolic activation and do not bind covalently to DNA (*2*). When a tumor promoter is painted periodically on mouse skin, following application of an initiator, papillomas develop. If treatment with the promoter is discontinued too soon, the papilloma regresses. However, when applied alone, the promoter may induce skin hyperplasia but does not generally induce papilloma (*3*). These data suggest that tumor promoters act "epigenetically" on the cells and their effects are reversible, whereas initiators genetically and irreversibly alter the cells.

At concentrations as low as 5×10^{-10} *M*, the phorbol diester tumor promoters, the most potent of which is TPA, induce a number of biologic and biochemical effects on cells in vitro. These effects include alterations in surface receptor, cell morphology, cell growth pattern, saturation density, cell-to-cell communication, anchorage dependence, membrane transport, and cyclic nucleotide synthesis, stimulation of mitoses and cell glycoproteins, induction of plasminogen activator and ornithine decarboxylase, modulation of cell differentiation, induction of oncogenic viruses, and enhancement of virus-induced cell transformation (*4–15*).

Among the pleiotropic effects of TPA, some changes (e.g., in morphology, cell adhesion, or inhibition of epidermal growth factor binding to membrane receptors) occur immediately or within a few hours after TPA treatment and do not require macromolecular synthesis (*16, 17*). This observation suggests that these changes are caused by the direct interaction of TPA with the cell membrane.

These facts prompted us to investigate the influence of TPA on C3 receptors and EBV receptors on the surface of a number of cell types including cell lines originating from a healthy adult, from Burkitt's lymphoma, and from T-cell leukemia. The results show that treatment with TPA decreases the number of C3 and EBV receptors at the same time in the several lymphoblastoid cell lines. However, in one cell line, significant stimulation of rosette formation was observed.

MATERIALS AND METHODS

Cells and viruses.—All cell lines were maintained in RPMI-1640 medium (Flow Laboratories, Inc., Irvine, Scotland) supplemented with 10% fetal calf serum, 100 IU penicillin/ml, and 100 µg streptomycin/ml. They were passaged routinely once weekly. The origin of each cell line is described in table 2. Infectious EBV was obtained from supernatants of P3HR-1 cells by differential centrifugation and concentrated about a hundredfold as described (*18*). SB4 cells were subcloned by the use of soft agarose (*18*). Cells were suspended at appropriate dilutions in 2 ml of RPMI-1640 medium containing 20% fetal calf serum and 0.35% sea plaque agarose (Marine Colloids, Inc., Rockland, Maine) and seeded in a 60-mm plastic petri dish containing a 5-ml base layer of 0.5% agarose in the same medium. The plates were then placed in a 5% CO_2 atmosphere at 37°C in a humidified incubator. Individual colonies were isolated by aspiration through the soft agar after 3 weeks from plates containing no more than 10–20 colonies.

Chemicals.—TPA, AMD, CH, Ara-C, IdUrd, and PM were purchased from Sigma Chemical Co., St. Louis, Mo.

ABBREVIATIONS USED: AMD=actinomycin D; Ara-C=β-cytosine arabinoside hydrochloride; CH=cycloheximide; DMSO=dimethyl sulfoxide; EA=early antigen(s); EAC=erythrocyte-antibody-complement; EBV=Epstein-Barr virus; IdUrd=5-iodo-2′-deoxyuridine; PM=puromycin; RA=13-*cis*-retinoic acid; SRBC=sheep red blood cells; TPA=12-*O*-tetradecanoylphorbol 13-acetate.

TEXT-FIGURE 1.—Effect of various concentrations of TPA on EAC rosette formation in Raji and SB4 cells. Raji (A) and SB4 (B) cells were incubated at a density of 4×10^5 cells/ml. Five days after addition of various concentrations of TPA, the percentage of EAC rosette-forming cells was determined as described in "Materials and Methods."

4α-phorbol-12,13-didecanoate and Ingenol prepared as previously described (*19*) were supplied by Dr. E. Hecker, Deutsches Krebsforschungszentrum, Heidelberg, Federal Republic of Germany. RA was obtained from Nordmark Co., Hamburg, Federal Republic of Germany. TPA and all other chemicals were dissolved in DMSO and phosphate-buffered saline, respectively.

Preparation of EAC.—A 1.5% suspension of washed SRBC was mixed with an equal volume of anti-SRBC antibody, diluted to one step lower than the agglutinating titer, and incubated at 37°C for 30 minutes. To this mixture an equal volume of fresh mouse serum diluted 1:20 was added and incubated at 37°C for 15 minutes. The preparation was placed on ice and used within 1 day.

EAC rosette assays.—Target cells, 2×10^5, were incubated with 2×10^7 EAC in a total volume of 300 μl medium for 5 minutes at room temperature, then centrifuged at 200×*g* for 5 minutes, and incubated again at room temperature for 20 minutes. Afterward, the cells were gently resuspended and kept on ice until they were counted. We determined the portion of rosette-forming cells (≥3 bound indicator cells/target cell) by viewing about 200 viable target cells on a glass slide.

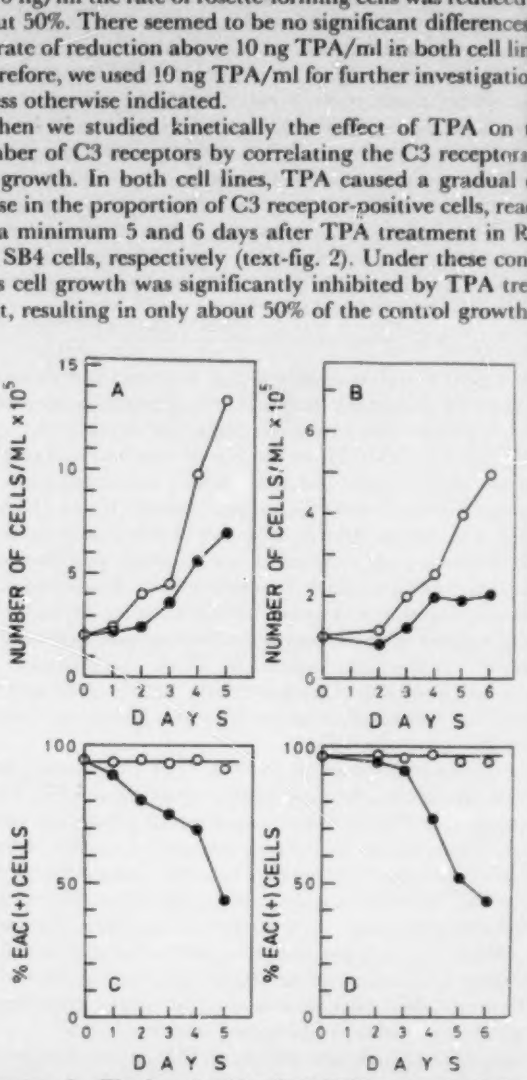
EBV receptors.—The concentration of EBV receptors was quantitated by the bioassay of Sairenji and Hinuma (*20*). An EBV concentrate from P3HR-1 supernatants was used as the virus source at a dilution of 1:8. In 10^6 Raji cells, 1 ml of this virus induced about 15% EBV-related EA-positive cells after 2 days. At intervals, TPA-treated and untreated cells were washed three times with complete medium and then suspended in 550 μl EBV. Incubation was continued at 37°C with gentle shaking. Thirty minutes after incubation, supernatants of the cultures were collected after centrifugation and processed for EA induction experiments, as described before (*20*). The adsorption index was calculated as described by Klein et al. (*21*) according to the formula: adsorption index = [maximal (control) % EA induction − test % EA induction]/maximal (control) % EA induction.

Treatment of the cells with TPA.—TPA was added to the tissue culture medium at the indicated concentration. Control cultures received DMSO alone.

RESULTS

First we investigated the effect of different concentrations of TPA on C3 receptors of Raji and SB4 cells. As shown in text-figure 1, EAC rosette-forming cells were significantly reduced 5 days after treatment with TPA in both cell lines. At 10 ng/ml the rate of rosette-forming cells was reduced by about 50%. There seemed to be no significant differences in the rate of reduction above 10 ng TPA/ml in both cell lines. Therefore, we used 10 ng TPA/ml for further investigations, unless otherwise indicated.

Then we studied kinetically the effect of TPA on the number of C3 receptors by correlating the C3 receptors to cell growth. In both cell lines, TPA caused a gradual decrease in the proportion of C3 receptor-positive cells, reaching a minimum 5 and 6 days after TPA treatment in Raji and SB4 cells, respectively (text-fig. 2). Under these conditions cell growth was significantly inhibited by TPA treatment, resulting in only about 50% of the control growth in



TEXT-FIGURE 2.—Kinetic study of the effect of TPA on growth of cells and on EAC rosette formation in Raji and SB4 cells. Raji and SB4 cells were incubated in the presence (●—●) or absence (○—○) of 10 ng TPA/ml at a density of 2×10^5 cells/ml and 1×10^5 cells/ml, respectively. At the indicated times the number of viable (trypan blue excluded) cells/ml was determined in a hemacytometer (Raji, A; SB4, B). At the same time the percentage of EAC rosette-forming cells was determined (Raji, C; SB4, D).

both lines. Viability of these cells, however, was not significantly affected by the presence of TPA. In a representative experiment with the use of Raji cells, viability was 83% 5 days after TPA treatment compared to 84% in control cultures. Raji and SB4 cells did not show significant differences after TPA treatment, as far as the viability of the cells was concerned. In contrast to TPA, no reduction in C3 receptors on Raji or SB4 cells was seen with two nonpromoting diterpenes, 4α-phorbol-12,13-didecanoate and Ingenol, used at concentrations of 1–100 ng/ml.

We then studied whether the reduction of C3 receptors caused by TPA was linked to that of EBV receptors. For this purpose we used the quantitative bioassay described by Sairenji and Hinuma (*20*). To avoid the complication arising from cell proliferation, we treated Raji cells with 5 μg of the DNA inhibitor Ara-C/ml. Under this condition cell growth was completely inhibited without affecting the rate of the C3 receptors (table 1). Text-figure 3 shows that the adsorption index decreased at the same time as the number of receptor-positive cells.

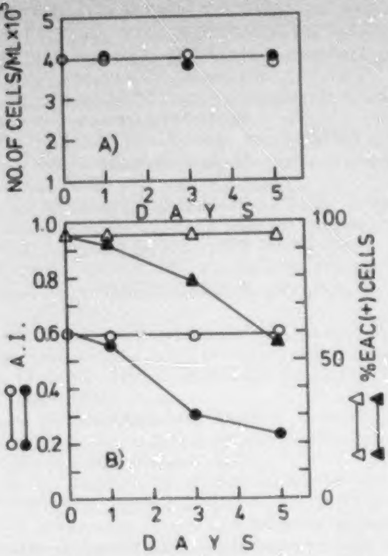
Further experiments were done to determine whether the TPA-induced reduction of C3 receptors was seen in other human lymphoblastoid cell lines and in subclones of SB4 cells. We tested 9 C3 receptor-positive cell lines that have some differences in their origins and in the EBV genome status. Table 2 shows that all tested cell lines, except BJAB cells, responded to TPA treatment. The extent of reduction of C3 receptors after TPA treatment seemed to vary greatly depending on the cells and lay between 15 and 75% of that seen in the control cultures. In BJAB cells, an EBV-negative Burkitt's lymphoma-derived line, rosette formation was significantly stimulated after TPA treatment. As compared to the reduction of rosette formation, a rather rapid response was seen, reaching a maximum 3 days after TPA addition (table 2). This effect was reproducible in two further experiments, although the enhancement of EAC rosette formation was not large.

TABLE 1.—*Effect of various inhibitors of macromolecular synthesis on the TPA-induced reduction of C3 receptors in Raji cells*

Treatment[a]	Percent EAC at:[b]	
	3 days	5 days
AMD (100 ng/ml) + TPA	71±6	45±5
CH (5 μg/ml) + TPA	56±7	40±3
PM (5 μg/ml) + TPA	50±6	41±3
Ara-C (10 μg/ml) + TPA	61±8	57±5
IdUrd (10 μg/ml) + TPA	61±6	59±8
RA (10 *μM*) + TPA	67±10	56±12
TPA	65±11	54±11
AMD (100 ng/ml)	87±8	81±9
CH (5 μg/ml)	92±4	87±1
PM (5 μg/ml)	78±8	71±6
Ara-C (10 μg/ml)	91±4	90±5
IdUrd (10 μg/ml)	90±8	91±5
RA (10 *μM*)	93±3	88±8
No treatment (control)	93±10	89±9

[a] In the presence of inhibitors the appropriate macromolecular syntheses were inhibited completely within 24 hr without affecting the cell viability. In all instances, TPA was administered at 10 ng/ml.

[b] Percent of EAC rosette-forming cells. Values are means ± SD of triplicate assays.



TEXT-FIGURE 3.—Comparative study of the effect of TPA on C3 and EBV receptors in Raji cells. Cells were incubated with Ara-C (5 μg/ml) at a density of 4×10⁵ cells/ml in the presence or absence of TPA. At intervals, the number of viable cells was determined (A). At the same time, the adsorption index (A.I.) [●——● (+TPA); ○——○ (−TPA)] and EAC rosette-forming cells [▲——▲ (+TPA); △——△ (−TPA)] were determined as described in "Materials and Methods" (B).

Finally, we investigated the effect of various inhibitors of macromolecular synthesis on the TPA-induced reduction of C3 receptors of Raji cells. Table 1 shows that in the presence of an inhibitor of RNA synthesis (AMD) and of inhibitors of protein synthesis (CH and PM) together with TPA, some enhancement was seen in the reduction of C3 receptors even though these chemicals when used alone did not affect EAC rosette formation. Inhibitors of DNA synthesis (Ara-C and IdUrd) did not significantly affect the results. RA has been reported to inhibit various alterations induced by TPA (*22–24*). However, the results showed that RA did not inhibit the TPA-mediated reduction of C3 receptors.

DISCUSSION

Evidence is increasing that an early site of action of TPA is the cell membrane (*25–27*). For example, inhibition of the epidermal growth factor binding to receptors in HeLa cells occurs within a few minutes after exposure to TPA, and adhesion of murine erythroleukemia cells to the surface occurs within 20 minutes of addition of compound. The fact that these changes do not require de novo syntheses of RNA and protein also supports the assumption that tumor promoters have a direct effect on cell membranes and their functions (*16, 17*). The current studies show that the reduction of C3 and EBV receptors takes place much more slowly than do the above-mentioned alterations induced by TPA. This finding suggests that the decrease of C3 and EBV receptors is not caused by the direct action of TPA but rather by the indirect action. As far as the kinetic studies are concerned, our results resemble the decrease of large, external transformation-sensitive protein or induction of

EBV antigens after treatment with TPA, which also requires a few days for maximal expression (*5*). Some additional steps are apparently required after the initial interaction of TPA with the cell membrane, leading to the modification of the gene expression and to an increase or decrease in the various metabolites, proteins, and enzymes plus modifications of the differentiation of the cells.

Several lines of evidence suggested that phorbol esters have effects on cell differentiation. These effects include the inhibition of differentiation and, conversely, promotion of it. In the inhibition of differentiation, the phenotypes and cell types that are affected by phorbol esters vary greatly, e.g., hemoglobin synthesis in mouse Friend erythroleukemia cells, myotubule formation in chick myoblast, sulfated proteoglycan synthesis in chick chondroblast, lipid accumulation in mouse Balb/3T3 fibroblasts, neurite formation in mouse neuroblastoma cells, melanin synthesis in mouse melanoma cells, and changes in morphology and phagocytic activity in mouse myeloid leukemia cells (*6, 12, 28-32*). Among these cell types, mouse Friend erythroleukemia cells are used most frequently. These cells are induced to differentiate to produce benzidine by treatment with various chemicals (e.g., DMSO), and finally cell growth ceases after expression of such a phenotype. TPA inhibits reversibly this induction of cell differentiation. These data would support the idea that cancer cells arise from aberrant differentiation and that disturbance of differentiation may be involved in the promotion step of chemical carcinogenesis (*33*). However, several groups have found that tumor promoters also may stimulate several types of cell differentiation (*34-37*). These conflicting observations on cell differentiation were even seen in the experiments in which the same cell line was used. A murine myeloid leukemia cell line (M1 cells) has indeed shown both stimulation and inhibition of differentiation by phorbol esters (*34, 37*).

In the present studies C3 and EBV receptors in several lines were specifically reduced by TPA. In the EBV-negative cell line BJAB, the same treatment stimulated EAC rosette formation. Moreover, previous experiments have shown that after TPA treatment SB4 cells could be stimulated to produce IgG and to phagocytize *Candida* cells, while the concentration of Fc receptors was not affected (Mitsuma T, Vogt A, Takamiya H, Galli C, Yamamoto N: Manuscript in preparation). Conceivably, these alterations were also related to cell differentiation.

Table 1 shows that the inhibitors of RNA and protein syntheses enhanced the reduction of EAC rosette formation by TPA even though the chemicals per se had very little effect. It is likely that production of C3 receptor protein is inhibited and old receptor proteins decay gradually on the cell surface without being replaced by newly synthesized receptor proteins in the presence of these agents. At the moment, however, it is difficult to explain how these chemicals exert their effects on the TPA-induced reduction of EAC rosette formation. Inhibitors of DNA synthesis did not affect the EAC rosette formation when they were used alone or together with TPA. Similarly, RA had no effect on EAC rosette formation.

Under our experimental conditions TPA inhibited cell growth considerably, although both TPA-treated and untreated cultures did not show significant differences in cell viability at the termination of the experiments. The decrease of C3 and EBV receptors by TPA, however, is not attributable to this cell growth inhibition, since inhibitors of DNA synthesis do not decrease the number of C3 receptors even though they have stronger effects as far as growth inhibition is concerned.

A number of experiments have suggested that the receptor for EBV on B-cells is identical to or closely associated with the receptor for the C3 component of complement (*38*). It was therefore of interest to determine whether the decrease of C3 receptors is associated with that of EBV receptors after the treatment with TPA. Text-figure 3 shows that it is. This observation does not, of course, exclude the possibilities that the EBV receptor either includes components in addition to the complement receptor or is closely linked to but separate from the complement receptor. Nevertheless, the fact that these independent methods revealed the reduction of C3 and EBV receptors, respectively, suggests that the cell membrane containing these receptors was indeed modified by TPA.

TPA efficiently induces EBV-specific antigens in genome-carrying cells. In producer cell lines, not only viral antigens but also viral particles are induced, while induction is restricted only to the functional viral proteins, EA in nonproducer lines (*13*, *38*). Most of the cells that we used in the present study were EBV nonproducers or even EBV-negative cell lines. Therefore, the possibility that the decrease of C3 and EBV receptors was due to readsorption of induced virus particles onto these receptors, blocking them in the process, is clearly excluded. However, whether the effect is due to interaction of receptor protein with viral proteins remains to be determined.

The aim of the present study was to investigate the influence of TPA on C3 receptors and EBV receptors on the surface of various cell lines, including those originating from a healthy subject and from patients with tumors. The inhibitory effect of the tumor promoter TPA on EAC rosette formation was considered to be due to TPA itself, not to DMSO used as a solvent since the DMSO had no effect at any concentration used (≤0.1%). In addition, two nonpromoting diterpenes exerted no influence on C3 receptors. The present study adds one more effect to the panel of pleiotropic effects of TPA in vitro. Several authors have tried to correlate the level of such effects [e.g., (*16*, *19*)] caused by various tumor promoters with that of tumor-promoting activity in vivo. Further study will clarify whether other tumor promoters have similar effects and if their effects then parallel the degree of tumor-promoting activity.

Cerebrospinal Fluid Levels of 2′-Deoxycoformycin After Systemic Administration in Monkeys[1,2]

Julie Blatt,[3] Peter M. Venner,[4,5,6] Riccardo Riccardi,[3,7] Lawrence F. Cohen,[3] Diamon Gangji,[3,8] Robert I. Glazer,[4] *and* David G. Poplack[3,9]

ABSTRACT—2′-Deoxycoformycin (DCF) is an inhibitor of the enzyme adenosine deaminase (ADA) and has shown promise as an antileukemia agent. For the assessment of the extent to which systemically administered DCF crosses into the central nervous system (CNS), rhesus monkeys were given iv boluses of DCF. Simultaneous blood and cerebrospinal fluid (CSF) samples were assayed for DCF levels at times ranging from 10 minutes to 6 hours after the drug was given. Average peak CSF drug levels of 5.5×10^{-8} *M* and 3×10^{-7} *M* were reached 1½–2 hours following injections of 0.25 and 1.0 mg DCF/kg, respectively. The ratio of peak CSF to simultaneous plasma levels was 1 to 10. Data obtained from a patient who had acute lymphocytic leukemia and who was given iv DCF were comparable. Drug levels achieved within the CSF following iv administration of 0.25 mg DCF/kg are similar to those previously demonstrated to inhibit ADA. These results may be important both for understanding DCF-related CNS toxicity and for designing combination chemotherapy with DCF.—JNCI 1982; 68: 391–393.

DCF is a tight-binding inhibitor of the enzyme ADA and has shown promise as an antileukemia agent (*1–5*). In particular, the demonstration that lymphoblasts with T-cell characteristics have elevated ADA activity has raised the possibility that DCF might provide a means of selective chemotherapy for patients with T-cell ALL, a group known to have a poor prognosis with currently available chemotherapy (*6*). The systemic administration of DCF has been associated with dose-limiting toxicity to the CNS. Severe encephalopathy, seizures, confusion, and emotional lability have been noted (*1–3*). However, little information is available on the ability of DCF to cross the blood-brain barrier in primates, and the relationship of DCF levels in the CNS to toxicity is not known.

The concentration of DCF in the CNS may also be important because of the anticipated use of this agent in combination with Vira-A in anticancer clinical trials. The presence of DCF in the CNS in amounts sufficient to inhibit ADA might enhance the therapeutic efficacy or increase the toxicity of Vira-A within the CNS.

To better define the extent to which DCF crosses the blood-brain barrier, we administered DCF iv to rhesus monkeys and measured serial plasma and CSF drug levels. In addition, DCF levels were determined in plasma and CSF samples from 1 CNS leukemia patient who had participated in a phase I trial of DCF (*3*).

MATERIALS AND METHODS

Animals.—Four adult male rhesus monkeys (*Macaca mulatta*) weighing between 6.0 and 7.6 kg were obtained from the National Institutes of Health Primate Center. A subcutaneous Ommaya reservoir was placed in each animal as previously described (*7*) such that sterile ventricular CSF sampling could be accomplished over an extended period of time. All injections and sampling were performed on conscious animals sitting in primate chairs. Venous blood samples were obtained from a heparinized indwelling femoral vein catheter. Monkeys were monitored daily for 1 week after DCF administration for signs of toxicity with neurologic and ophthalmologic examinations, complete blood counts with platelet and differential counts, liver enzymes, blood urea nitrogen, and creatinine.

Humans.—One 6-year-old male with ALL participating in a phase I trial of DCF received iv 0.25 mg DCF/kg/day for 3 successive days. During and after a course of DCF therapy he underwent two lumbar punctures for evaluation of concurrent CNS disease. Aliquots of CSF as well as simultaneous plasma samples were assayed for DCF levels.

DCF preparation and administration.—DCF (NSC-218321) was obtained as Pentostatin from the Investigational Drug Branch, Division of Cancer Treatment, National Cancer Institute. A 2 mg/ml solution was prepared with the use of injectable sodium chloride. This solution was administered as an iv bolus via the femoral vein to each of 2 monkeys at a dose of 0.25 mg/kg and to another 2 monkeys at 1.0 mg/kg.

Sample collection and processing.—Samples of CSF, 0.25–1.0 ml, were obtained from the Ommaya reservoir before and periodically following iv injection of DCF (10, 30, 60, and 90 min and 2, 4, and 6 hr). Simultaneous venous blood samples were obtained and centrifuged, and the resultant plasma was removed. All specimens were frozen at −20°C until immediately before use in DCF assays.

DCF assay.—DCF activity in plasma and CSF was deter-

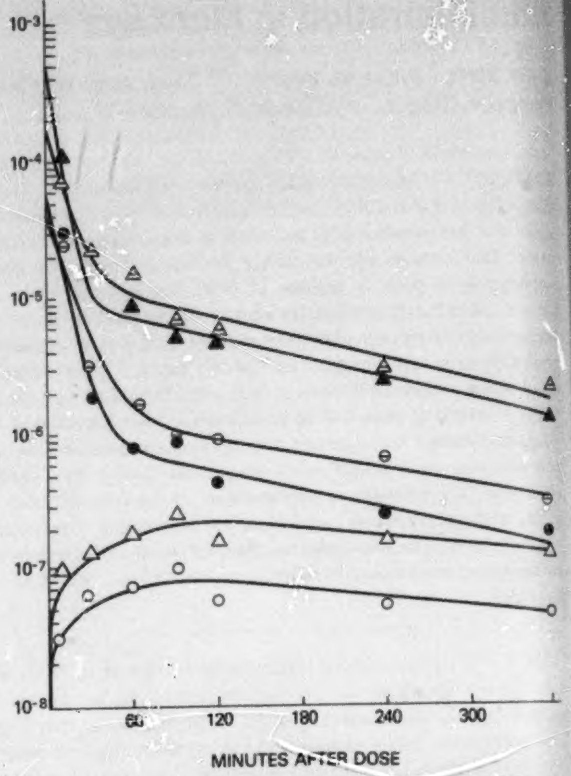
mined by inhibition of the ADA-catalyzed conversion of adenosine to inosine according to a previously described method (*8*). Samples were not boiled or filtered before DCF assay. Standard curves were determined by incubation of calf intestinal ADA (Sigma Chemical Co.), 0.0067 U, with known amounts of DCF (0.2–06 n*M*) in 0.05 *M* potassium phosphate buffer (pH 7.4) at 37°C for 10 minutes. Adenosine (final concentration, 0.1 m*M*) was then added for a total volume of 1.0 ml, and the reaction was followed at 265 nm with the use of a Gilford 250 spectrophotometer. A plot of DCF concentration versus percentage of control rate of adenosine deamination was used to calculate all plasma and CSF DCF levels. These levels were determined by the dilution of samples to cuvette concentrations so as to obtain a rate of 40–75% of the uninhibited control with the use of a reaction mixture as described above. The assay was validated by the addition of known concentrations of DCF to plasma and CSF.

Pharmacokinetics.—DCF serum levels were analyzed for pharmacokinetic parameters. Data were tested for statistical fit to one, two, or three compartment models according to general formulae (*9*). The best fit for serum data was a two-compartment open model described by $C = Ae^{-\alpha t} + Be^{-\beta t}$, where A, α refer to the fast, initial component and B, β to the terminal, slow component. A and B are the zero time concentrations of the respective components, and C is the total concentration at time t. The α and β are the elimination rate constants for the respective components. Calculations were made sequentially with A initially zero, and the respective components were tested for fit with the use of linear regression and the Pearson moment product of correlation. Calculations for the fast component were made with serum levels adjusted for the slow component elimination results. The curves for the serum data in text-figure 1 were generated from the equation above and the derived parameters. The curves for the CSF data were optically fit.

RESULTS

Plasma and CSF levels following iv bolus injection of 0.25 mg DCF/kg or 1.0 mg DCF/kg in the rhesus monkey are shown in text-figure 1. The α $t_{1/2}$ for plasma was 10–15 minutes and the β $t_{1/2}$ was 2 hours. Average peak CSF levels were 5.5×10^{-8} *M* and 3×10^{-7} *M* for the two dosages. These were reached 1½–2 hours after the drug was given. Peak CSF levels of DCF were one-tenth of simultaneous plasma levels.

Comparable data on CSF to plasma ratios were obtained from the samples available on 1 patient. Four hours after the first 0.25 mg/kg iv bolus, the DCF concentrations in the CSF and plasma were 7×10^{-8} *M* and 5.5×10^{-7} *M*, respectively. One hour after the third daily dose of DCF, the CSF level was 1.3×10^{-7} *M* with a concurrent plasma level of 9×10^{-7} *M*. Neither the monkeys nor the 1 patient developed any neurologic toxicity.



Text-figure 1.—Plasma and CSF levels of DCF. △, ▲: plasma DCF levels in each of 2 monkeys following 1.0 mg/kg iv bolus. ⊖, ●: plasma DCF levels in each of 2 monkeys following 0.25 mg/kg iv bolus. ○, △: CSF levels following 0.25 mg/kg iv bolus and 1.0 mg/kg, respectively.

DISCUSSION

DCF has been demonstrated to have activity against systemic ALL and is presumed to act by inhibiting ADA. In vitro studies have shown that levels of DCF of 4×10^{-8} *M* result in 50% inhibition of ADA in L1210 cells and that DCF levels of 5×10^{-7} *M* result in 100% ADA inhibition (*10*). Phase I studies in humans have suggested that doses greater than or equal to 0.25 mg DCF/kg iv can temporarily inhibit ADA in leukemia and normal white blood cells in bone marrow and peripheral blood (*1–5*).

In dogs, a single 0.25 mg/kg iv bolus of DCF has been found to reduce ADA activity of normal intracerebral tissue to 20% of base-line levels for at least 24 hours following peak CSF levels of only 1.5×10^{-8} *M* (*8*). Whether sufficient levels of DCF can be achieved in the CNS to inhibit ADA in resident leukemia cells following systemic drug administration is uncertain. The results of the present study are consistent with pharmacokinetics demonstrated in dogs and show that when DCF is given as a single iv bolus to rhesus monkeys, peak CSF levels of DCF are about one-tenth of simultaneous plasma levels. In addition, a recent study has shown similar ratios of peak CSF to simultaneous plasma levels in an ALL patient who was treated with multiple daily doses of DCF (*11*). Increases in drug dosage result in approximately linear increases in both plasma and CSF drug levels. Extrapolation from these results, for example, might suggest that a systemic dose of 0.5 mg/kg would produce peak CSF levels of approximately 10^{-7} *M*. On the basis of the above-mentioned human, L1210, and dog studies, these levels might be expected to inhibit ADA in normal monkey brain cells as well as ALL cells sequestered in the CNS. The applicability to humans of studies in monkeys on drug transport across the blood-brain barrier has already been established (*12*).

In a recent phase I trial, 0.5 mg DCF/kg/day for each of 3 successive days resulted in no significant neurotoxicity (*3*). None of the monkeys studied here given either 0.25 mg DCF/kg or 1.0 mg DCF/kg demonstrated neurotoxicity. Thus results of the present study do not permit a definitive statement regarding the relationship of either DCF levels or ADA inhibition within the CNS and the production of neurotoxicity. Measurement of ADA activity in ALL cells in the CSF before and after systemic DCF administration and correlation with neurotoxicity will be of interest.

Smoking History and Lung Cancer Survival in Women[1,2]

M. Ward Hinds, *M.D., M.P.H.,*[3] **Hong-Yi Yang,** *M.D.,*[4] **Grant Stemmermann,** *M.D.,*[5] **James Lee,** *Ph.D.,*[3] *and* **Laurence N. Kolonel,** *M.D., Ph.D.*[3,6]

ABSTRACT—The 12-month survival of 223 women with primary lung cancer was examined according to their smoking status given in the hospital record. A multivariate regression model was used to adjust simultaneously for age, tumor stage at diagnosis, tumor histology, and treatment. With adjustment for all these covariates, the 136 ever-smokers demonstrated a significantly greater probability of dying during the 12 months after diagnosis than the 87 never-smokers (odds ratio=1.74; *P*=0.023).—JNCI 1982; 68:395–399.

Many nontherapeutic factors have been associated with survival of patients with lung cancer. These factors include age (*1–3*), sex (*1, 2*), race (*2, 4*), socioeconomic status (*2, 5*), tumor histology (*1, 6, 7*), pretreatment performance status (*3, 7*), disease stage (*2, 3, 6, 7*), weight loss history (*3*), and pattern of metastases (*3*). Still another factor, smoking status, was recently suggested to have prognostic value for patients with small cell lung cancer (*8*); patients who had never smoked or quit smoking before diagnosis had the best survival, patients who quit at the time of diagnosis had intermediate survival, and patients who continued smoking had the worst survival. An earlier study (*9*), however, found no association between smoking history and lung cancer survival. Experimental studies of murine tumor cell transplants lend some support to the hypothesis that exposure to cigarette smoke may promote tumor growth and decrease survival (*10*).

We recently investigated the relationship of smoking to lung cancer risk among Japanese, Chinese, and Hawaiian women in Hawaii (*11*) and found that a substantial proportion of lung cancer patients in these groups had never smoked. When we further examined the survival of these women with respect to their smoking status, we found that those who had never smoked demonstrated superior survival. The details of this finding are reported herein.

METHODS

The method of identification of the lung cancer patients through the HTR has been described in detail elsewhere (*11*). All patients were Japanese, Chinese, or Hawaiian–part-Hawaiian women diagnosed with primary lung cancer from 1968 to 1978. Smoking histories were obtained by a review of the medical records, and a patient was not considered a never-smoker unless specifically so called in her record. Patients with any history of smoking were classified as smokers. Lack of record detail precluded quantification of smoking history. Pathology slides were independently reviewed by two of us (H. Y. Y. and G. S.). When independent slide reviews were not in agreement (16%), mutual agreement was reached in a joint review. The pathologists reviewing the slides were kept blind to all information about the patient.

We included in our survival analysis only those patients for whom we knew age and stage at diagnosis, smoking history, initial treatment, and follow-up status for at least 12 months post diagnosis and for whom the pathologic slide review indicated an epidermoid, adenocarcinoma, small cell, or large cell histologic pattern. We were thus able to include in the survival analysis 223 of the original 397 patients identified by the HTR. The remaining 174 patients could not be included because their records were not found (No.=22), readable tissue slides were not available (No.=84), smoking histories were not present in the records (No.=55), an unusual histologic pattern was found (No.=7), or the stage at diagnosis was unknown (No.=6).

Staging categories used were as follows: *a*) *localized*—restricted to the lung, *b*) *regional*—spread by direct extension to immediately adjacent tissues or organs and/or spread into regional lymph nodes, and *c*) *distant*—spread beyond immediately adjacent tissues or organs or regional lymph nodes. Staging was standardized by a review of all 223 HTR abstracts.

The first course of cancer-directed therapy was coded by the HTR. We categorized treatment as surgery alone, radiation alone, or other modalities (primarily chemotherapy) alone or in combination. Further subcategorization was possible but not practical due to the small number of patients in each subcategory.

Using the proportional hazards regression model described by Prentice and Gloeckler (*12*), we compared the survival experience of smokers versus never-smokers. This multivariate method allows examination of the influence of any single factor on survival while simultaneous adjustment can be made for other factors (covariates) in the model. We included the following covariates in various stages in our model: age, ethnic group, disease stage at diagnosis, treatment, and tumor histology. We computed the covariate-adjusted relative risk of dying in smokers compared to never-smokers. Using a rationale and method similar to those described by Lee (*13*) for the logistic regression model, we further computed interval-specific covariate-adjusted sur-

vival rates. Survival analysis was restricted to 12 months after diagnosis because 56% of the patients were deceased by that time, and the small number of patients remaining after 12 months would not allow convergence of the iterative procedure of the computer program while all covariates were included in the model.

RESULTS

As can be seen in table 1, smokers and never-smokers differed in their distribution of all of the covariates, although the differences were statistically significant ($P<0.05$) only for age, ethnic group, and tumor histology. As would be expected, smokers tended to be younger than never-smokers, epidermoid and small cell cancers were more common among smokers, and adenocarcinomas were more common among never-smokers. Smokers were also more likely to be Hawaiian. However, since our survival analyses consistently showed that ethnicity of these lung cancer patients was not significantly related to their risk of dying, ethnicity was omitted as a covariate in the final analyses. Although neither disease stage at diagnosis nor treatment was significantly related to smoking status, the distribution of both would tend to favor better survival of never-smokers because more never-smokers were diagnosed while their disease was still in a localized stage and more were treated with surgery only. Stage of disease at diagnosis has been consistently shown to be a strong predictor of survival (*2, 3, 6, 7*), and our analysis likewise showed this tendency so that this covariate was included in the model to preclude any stage bias in favor of the survival of never-smokers. Our analysis suggested that treatment was only a weak predictor of survival after adjustment was made for other covariates, however, so that analyses both with and without adjustment for treatment are reported.

When adjustments were made for age, stage, and histology, the multivariate model gave a relative risk of 1.86 ($P=0.011$) for dying within 12 months of diagnosis among smokers compared to never-smokers. As would be expected, age, stage, and histology were also significantly ($P<0.05$) related to risk of dying in this model. When treatment was added to the model, the relative risk of dying among smokers compared to never-smokers was slightly reduced to 1.74 ($P=0.023$). However, as noted above, treatment itself was not quite significantly related ($P=0.075$) to risk of dying in this model. Age, stage, and histology remained significantly related to risk of dying in the model including treatment.

We present a model-independent description of the survival of never-smokers versus smokers within several age, stage, and histology strata in table 2. Because the degree of stratification used in the regression model (and shown in table 1) resulted in very small numbers in some cells, several strata were collapsed in table 2. The superior survival of never-smokers versus smokers is evident in six of the eight strata, with the only exceptions being patients less than age 65 with distant disease stage and nonadenocarcinoma histology and patients over age 64 with localized or regional disease stage and adenocarcinoma histology.

Because histology appeared to have the greatest potential for confounding the smoking status–survival association, we performed a separate multivariate regression analysis of adenocarcinoma cases only, again comparing the survival of smokers and never-smokers while simultaneously adjust-

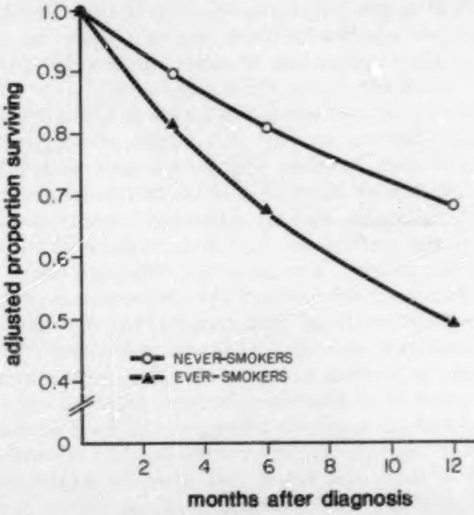
ing for age, tumor stage, and treatment. We found a relative risk of 2.1 (P=0.057) for dying within 12 months of diagnosis among smokers compared to never-smokers. Thus although statistical significance was borderline, the superior survival of never-smokers found in the analysis of all cases was supported in the analysis of adenocarcinoma cases alone.

Because treatment of lung cancer has been changing substantially and because there is evidence that survival of lung cancer patients is improving (*4*), we considered the possibility that our comparison of survival among smokers versus never-smokers might be biased by more never-smokers having been diagnosed and treated in the latter part of the study period. However, as shown in table 3, there was no statistically significant difference in the distribution of smokers and never-smokers with respect to time period of diagnosis. Such differences as did exist would favor a better survival of smokers because more were diagnosed in the latter part of the study period.

In text-figure 1 we show the model-predicted survival curves for smokers and never-smokers after adjustment for age, disease stage at diagnosis, and tumor histology. This model predicts that 68.1% of never-smokers but only 49.1% of smokers with lung cancer would be living at 12 months after diagnosis.

DISCUSSION

The findings of this investigation and those of Johnston-Early et al. (*8*) suggest that smoking status of lung cancer patients may be an independent predictor of survival. Such a conclusion is, however, in contradiction to the findings of Linden et al. (*9*) in an earlier study. Although these disparate results cannot be easily reconciled, it is worth noting several characteristics of the study of Linden et al. that make its results difficult to interpret. Although 5% of the cases were not histologically confirmed, they were nevertheless included as lung cancers. Perhaps more importantly, 43% of the cases had no specific histologic classification other than "carcinoma." Thus any adjustment for histology in the survival analysis (none was attempted) was precluded. However, the available histologic data of Linden et al. indicated that the survival for squamous carcinoma patients was superior to that for adenocarcinoma patients up to 27 months after diagnosis and that squamous carcinoma patients were more likely to be smokers. Therefore, a bias favoring survival of smokers is suggested. Similarly, there was no attempt to adjust for age in the survival comparisons, although it was stated that a higher proportion of nonsmokers were age 65 or older. Because older age is associated with decreased survival, this again suggests a bias favoring better survival of smokers. The number of never-smokers was very small (No.=15), and there was no attempt to identify those who may have stopped smoking before their lung cancer diagnosis. Finally, the cases in the study of Linden et al. were diagnosed over a broad time period (1953–68), and there was no attempt to examine the data to see if the smoking categories of cases were distributed by time of diagnosis in



TEXT-FIGURE 1.—Model-predicted survival curves for ever-smokers and never-smokers with lung cancer after simultaneous adjustment for age, disease stage at diagnosis, and histologic classification of tumor. The curves are significantly different (P=0.01).

a manner that might favor survival of smokers. Considering all these shortcomings, it is not difficult to see how Linden et al. (*9*) might have failed to detect a survival advantage among nonsmokers of the small magnitude suggested by our findings and those of Johnston-Early et al. (*8*).

One shortcoming of our own study is the lack of information on pretreatment performance status of the lung cancer patients. Performance status is a very strong predictor of lung cancer survival (*7*) and is now routinely controlled for by stratified randomization in lung cancer treatment studies (*14*). Unfortunately, performance status of our patients was not available from the HTR records. The study of Johnston-Early et al. (*8*), however, did contain information on performance status, and they found no statistically significant association between this variable and smoking status. Nevertheless, they adjusted for performance status in one analysis comparing survival of patients according to smoking categories and found that survival differences remained significant ($P<0.04$). Therefore, although we could not examine the effect of adjusting for performance status in the current study, the findings of Johnston-Early et al. (*8*) suggest that such adjustment would be unlikely to alter our results.

Our adjustment for treatment had only a small effect on the association between smoking status and lung cancer survival. When Johnston-Early et al. (*8*) adjusted for treatment protocol in a similar fashion, they also found that the association between smoking status and survival remained significant ($P<0.04$). We could find no significant difference in the treatment given to smokers compared to never-smokers, and such difference as existed was primarily related to the earlier disease stage at diagnosis among never-smokers and their different histologic pattern of lung cancer (more adenocarcinomas). Adjusting for stage and histology thus largely adjusted for treatment also, which possibly explains the lack of statistical significance for the association of treatment and survival in the multivariate model. Attempting to subcategorize treatment more finely than in table 1 did not suggest any bias favoring survival of never-smokers. In fact, a larger percentage of never-smokers (10.3%) received no treatment than did smokers (7.4%).

Two survival-related covariates (age and histology) were significantly different in their distribution among smokers and never-smokers. Smokers with lung cancer tended to be younger and to have more often either epidermoid or small cell tumor histologies. The age difference is understandable in view of the well-known higher prevalence of smokers among young women. The histologic difference is also understandable in consideration of the higher relative risk for epidermoid and small cell lung cancers than for adenocarcinoma associated with smoking in this population (*11*).

The findings of some animal studies may have relevance to the question of an association between smoking and lung cancer survival. Holt and his colleagues (*15*) have examined the effects of cigarette smoke exposure on the cell-mediated immunity of mice and found that exposure to the body-weight equivalent of 20–30 cigarettes a day results in substantial changes in immunologic function, both systemically and locally in the respiratory tract. Most interesting are the effects of cigarette smoke exposure on the growth rates of murine tumor cells inoculated sc and intratracheally (*10*). Mice exposed to cigarette smoke for 26 weeks and then inoculated sc with tumor cells showed significantly greater mean tumor volumes after day 14 post inoculation than did mice not smoke exposed. In addition, smoke-exposed mice developed significantly more lung metastases. In mice inoculated intratracheally with tumor cells, 70% of smoke-exposed animals died within 60 days compared to only 25% of controls (*10*).

If an independent relationship does exist between smoking status and cancer survival, it may not be limited to lung cancer. A study of patients with malignant melanoma suggests that nonsmokers remain disease-free significantly longer than do smokers (*16*). A general effect of smoking on cancer survival might be expected if the effect were mediated through alteration in immunologic functions (*15*).

The current study and other studies (*8*, *10*) suggest that lung cancer survival may be independently related to smoking status. The question of such an association is an important one with implications for the design and analysis of lung cancer treatment protocols. Furthermore, at least one study (*8*) suggests that some survival benefit may be derived by cessation of smoking at the time of lung cancer diagnosis. Although the current study cannot directly address this issue, the results do suggest the need for future research designed to do so. Such research with larger data sets that allow control for pretreatment performance status as well as other potentially confounding variables is needed before any conclusions can be reached about the true nature of the relationship between smoking status and lung cancer survival.

Intestinal Metaplasia in Japan: Association With Diet[1,2]

Abraham Nomura,[3] Hiroshi Yamakawa,[4] Takuzo Ishidate,[5] Sigetosi Kamiyama,[5] Hisayuki Masuda,[5] Grant N. Stemmermann,[3] Lance K. Heilbrun,[3] *and* Jean H. Hankin[6,7]

ABSTRACT—Of 1,749 volunteers in a screening program for gastric cancer in Japan, 206 men and 181 women received a systematic gastroscopic examination and responded to a dietary questionnaire estimating their quantitative intake of 33 food items during the past week. When diet was correlated with intestinal metaplasia (a precursor lesion of gastric carcinoma) found in gastroscopic biopsies, it was observed that more dried fish consumption and less vitamin A intake increased the extent of intestinal metaplasia in men. For women, there was a significant negative association of ume (pickled plum) intake with intestinal metaplasia. The implications of these findings were discussed in relation to gastric cancer.—JNCI 1982; 68:401–405.

Intestinal metaplasia of the stomach is considered to be a precursor lesion of intestinal gastric carcinoma as defined by histologic criteria (*1*). Many studies have consistently supported this view (*2–13*). For this reason, we decided to study the relationship of intestinal metaplasia with diet among the Japanese in Japan who are at high risk for gastric carcinoma.

Although many case–control studies of diet and gastric cancer have been done in the past (*14–21*), the interpretation of their findings has been cautious, partly because of the acknowledged long interval from gastric cancer induction to clinical manifestation (*22, 23*). Much reliance must be placed on the assumption that dietary information obtained after diagnosis reflects a person's usual diet over a long time. By the study of intestinal metaplasia, a precursor lesion, the time between exposure and the presence of disease is shortened considerably.

MATERIALS AND METHODS

Chokai Village is a rural community in Akita prefecture, Japan, with a population of 9,082 according to the 1975 National Census. From 1973 to 1978, 1,749 adult volunteer residents of Chokai Village received a fluoroscopic examination for the early detection of gastric cancer. On the basis of fluoroscopic findings or other clinical indications, 419 (24% of 1,749) subsequently received a gastroscopic examination along with a diet questionnaire. This report is limited to the 387 (92.4% of 419) subjects who systematically had a gastric biopsy taken from each of five sites in the stomach, as numbered and illustrated in text-figure 1.

Each biopsy specimen was assessed for the presence of intestinal metaplasia and was graded as follows: grade 0 = none; grade 1 = the presence of a single metaplastic gland; grade 2 = intestinal metaplasia involving two or more glands; grade 3 = intestinal metaplasia of the entire specimen. As a consequence, the intestinal grade scored for each subject ranged from 0 to 15 (five sites with a maximum grade of 3 each).

The participants were asked questions relating to education, occupation, cigarette smoking, alcohol intake, and recent dietary intake. Details of the dietary method used in this study have been previously published (*24*). We designed the study to quantitate the recent intakes of 33 specific food items by asking the participants to choose appropriate photographs of weighed small, medium, and large portions of each item. The 33 items were selected because of their suspected association with gastrointestinal neoplasms. The method consisted of an item-by-item recall to learn which items were eaten during the past week. When the respondent recalled eating a particular item, the interviewer asked him or her to choose the serving size from the picture. The dish in the photograph was present at the time of interview to provide the respondent with a sense of scale. The frequency of consumption and the estimated amount consumed during the past week were then recorded. For example, if a person ate three large servings of eggs (two eggs or 100 g) during the past week, his or her egg consumption was coded "3" for frequency and "3" (which designated large serving) for amount. The quantitative weekly amount would then be equivalent to 300 g (3×100 g).

Vitamin A and vitamin C intake was estimated mainly from food composition tables (*25, 26*) applied to the 33 food items. There were 16 food items containing varying amounts of vitamin A, and 11 containing varying amounts of vitamin C.

Age- and sex-adjusted mean metaplasia scores by cigarette use, alcohol use, and demographic variables were computed by the direct method of adjustment (*27*). The entire set of 387 subjects was the reference population. Comparisons of these mean metaplasia scores involved *t*-tests for independent samples.

The percent of subjects who consumed a given food item at least once during the week ranged from 1 to 98. As a result, 3 consumption-level groups (g/wk) in the analysis of the 33 food items were defined: none or low, intermediate, and high. To permit good estimates of age-adjusted mean metaplasia scores, we arbitrarily required at least 10 subjects in each of the 3 groups. Cutoff points were chosen accordingly for each food item. For vitamins A and C, 3 consump-

ABBREVIATION USED: *r*=coefficient of correlation.

TEXT-FIGURE 1.—1=the lesser curvature at the junction of the antrum with the corpus and roughly corresponding with the incisura—the area most likely to show intestinal metaplasia; 2 = the greater curvature of the pyloric antrum 2–4 cm proximal to the pyloric ring—an area at intermediate risk for intestinal metaplasia; 3=the greater curvature of the stomach opposite the incisura; 4=the lesser curvature midway between the incisura and cardia; 5=the greater curvature opposite site #4. The last three sites are areas of low risk for intestinal metaplasia.

tion level groups (low, intermediate, high) were defined with approximately equal numbers of subjects. For both men and women, the same nine foods did not meet the sample size criterion: beef, Spam–lunchmeat, bacon, dried cuttlefish, corn on the cob, cut corn, tomato juice, celery, and black tea. For the remaining 24 foods and for vitamins A and C, age-adjusted mean metaplasia scores by consumption level were computed by the direct method of adjustment (*27*).

Preliminary data analysis indicated major differences in the foods that were most related to extent of metaplasia in males compared with females. Therefore, the described food consumption categories, age adjustments, and all subsequent analyses were done separately by sex. As an initial variable-screening step, a test for (linear) trend in the metaplasia scores with increasing consumption of each food item and vitamin was done by means of bivariate regression (*28*), which accounted for age. Dietary items were retained for subsequent multivariate analysis if they showed notable linear trends ($P<0.15$) in metaplasia scores. Multivariate analysis of the relationship of metaplasia score to age and the selected dietary items was done (separately by sex) with ordinary multiple linear regression (*28*).

RESULTS

A total of 206 men and 181 women had the diet questionnaire and gastric biopsies from the five specified sites. The age range of the study subjects at time of examination was 22–78 years. The distribution of metaplasia score by sex and age is presented in table 1. The presence of extensive intestinal metaplasia peaked at ages 50–59 in men. In women, extensive metaplasia continued to increase with age.

Table 2 shows comparisons of metaplasia scores by social or personal characteristics. Although consumers of hard liquor had a lower average metaplasia score than nonconsumers, there was a lack of consistency in metaplasia scores between consumers and nonconsumers of different types of alcoholic beverages. Farmers had a higher mean metaplasia score than subjects with other occupations, but the difference was not significant ($P=0.06$).

The notable trends in mean metaplasia scores with increasing consumption of different foods and vitamins are shown separately for men and women in table 3. For men, the dietary items most related to metaplasia score were dried fish, saimin or udon (noodles), vitamin A, sashimi (raw fish), tsukudani (seaweed paste), fruit drinks–ades, and shrimp. Dietary items with $P>0.15$ for linear trend for men were chicken, wieners, Vienna–pork sausage, eggs, char siu (sweetened roast pork), kamaboko (fish cake), tofu (soybean curd), rice, Japanese soup, sliced tomatoes, lettuce, hakusaizuke (pickled Chinese cabbage), takuwan (pickled turnip), ume (pickled plum), green tea, genmai cha (tea), coffee, milk, and vitamin C. For women, foods most related to metaplasia score were only ume, chicken, and shrimp.

TABLE 1.—*Distribution of metaplasia scores by sex and age*

Sex	Age, yr	No. of subjects by metaplasia scores (%)

[a] Results are listed in descending order of statistical significance, except for the constant term of the multiple regression model.

[b] n=No. of subjects; R^2=proportion of total variation in metaplasia scores explained by the particular set of variables in the regression model.

[c] $\hat{b}$=estimated (unstandardized) regression coefficient.

[d] SE, $\hat{b}$=estimated standard error of $\hat{b}$.

[e] $\hat{\beta}$=estimated standardized regression coefficient. NA=not applicable.

[f] For testing (via *F*-statistics) whether the regression coefficient is significantly different from zero.

Table 3 suggests that seven dietary items should enter into the multiple regression analysis for men. However, vitamin A and fruit drinks–ades were too highly intercorrelated ($r=0.64$) to permit both of them in the model. Since vitamin A initially had the more significant association ($P=0.017$) and since it represents a summary measure of 16 foods, it was selected in preference to fruit drinks–ades.

The results of the multiple regression analyses, in which the simultaneous effects of age and the various dietary items can be assessed, are shown in table 4. For men, increasing metaplasia scores were significantly associated ($P<0.05$) with increasing age, increasing consumption of dried fish, and decreasing consumption of vitamin A. For women, however, increasing metaplasia scores were significantly associated with increasing age and decreasing consumption of ume.

DISCUSSION

The presence of intestinal metaplasia is common in this study population. Its greater prevalence in men than women and its increase with age have been previously reported (*29*). The systematic biopsies of the gastric mucosa represented only a very small portion of the gastric mucosal surface area. For this reason, subjects with focal metaplasia may have false-negative biopsies. The metaplasia score, therefore, probably underestimates the extent of metaplasia in the stomachs examined.

Alcohol intake in general and cigarette smoking in particular did not appear to be clearly associated with the degree of intestinal metaplasia. A separate investigation found that alcohol drinkers or current smokers had a slightly lower prevalence of precursor lesions such as intestinal metaplasia or chronic atrophic gastritis than was found for nondrinkers or nonsmokers, respectively (*11*). The authors attributed this pattern to a tendency to discontinue use of items that exacerbated gastric symptoms. With respect to stomach cancer, the findings from earlier studies on the use of alcohol have been equivocal (*15, 18, 30*). A positive association between cigarette smokers and stomach cancer has been observed mainly in prospective studies (*31, 32*), but the lack of a dose-response relationship has suggested that the association was not a causal one.

Haenszel and co-workers (*11*) found a negative association of precursor lesions of stomach cancer with social class status, which is consistent with the view of many past studies (*15, 18, 33, 34*) that stomach cancer is a disease of the low social class. We observed that farmers (low social class) had a notably ($P=0.06$) higher mean metaplasia score than persons engaged in other occupations.

Regression analysis revealed that more dried fish consumption and less vitamin A intake in men and less ume intake in women increased the extent of intestinal metaplasia. Dried fish is a common protein source in Chokai Village with an average weekly consumption of 626 g for men and 604 g for women. It consists mainly of dried sardine, cod, mackerel, or herring, with salt often included. The positive relationship of dried fish with its high salt content to intestinal metaplasia corresponds with findings in a previous study that showed a strong association between salt use and intestinal metaplasia (*35*). Workers have shown that dried fish is rich in nitrites or secondary amines (*36*), which are needed in the formation of N-nitroso compounds. N-nitroso compounds are known carcinogens (*37*), and some workers suspect that they may be associated with the development of gastric cancer (*1*).

Recent studies have suggested that low vitamin A intake may increase susceptibility to cancer (*38, 39*). Our findings among the men indirectly support this impression. Because vitamin C blocks the formation of N-nitroso compounds in vitro or in vivo (*40, 41*), it may be protective against gastric neoplasms. However, our data showed no association between vitamin C intake and the degree of intestinal metaplasia. On the basis of the 1975 National Nutrition Survey in Japan, the average daily intake for all persons of vitamins A and C was 1,602 IU and 117 mg, respectively (*42*). The average daily intakes for the adults in our study were 2,006 IU of vitamin A and 39 mg of vitamin C. The low level of vitamin C intake, as measured by our dietary questionnaire, may have contributed to its lack of association with intestinal metaplasia.

The reasons for the sex difference in the association of intestinal metaplasia with dried fish intake and vitamin A intake are not readily apparent. Several possibilities need to be explored, such as subtle differences in food use between the sexes. It is a common household custom in rural Japan for the husband to be served from the anterior portion of the fish. This would expose him to a higher salt intake if the body cavity of the fish has been packed with salt as part of the preservation process. It is also possible that women in this population might have a higher intake of substances that block the nitrosation of dietary amines.

Even though the mean weekly intake of ume was only 9 g, it had a significant negative association with metaplasia score in women. This was an unexpected finding because the process of pickling has been shown to increase the nitrite content of food items (*36*). Ume and other pickled items were found to be positively associated with stomach cancer among the Japanese in Hawaii (*15*) but not in Japan (*16*). When we correlated the intake of ume with the other 32 food items for the women, we found that it was strongly associated with only tomatoes (r=0.17) and celery (r=0.18), vegetables that have been negatively associated with stomach cancer in past studies (*14-16, 18*). The women had a higher mean weekly intake than did the men for tomatoes (136 vs. 85 g) and celery (11.8 vs. 9.4 g). Although this negative association of ume with metaplasia score possibly is a chance finding, further clarification is needed with regard to this observation.

Overall, only dried fish of the 33 food items in the questionnaire had a significantly positive association with intestinal metaplasia of the stomach. Several past studies have also shown that dried or salted fish increased the risk for gastric cancer (*14, 15, 18*). Because dried fish is so commonly consumed in Chokai Village and elsewhere in Japan, it is important to study further its relationship to intestinal metaplasia and stomach cancer.

Basis for the Differential Action of Aminonucleoside on Normal and Transformed Human Fibroblasts[1, 2]

Ernest A. Albanese[3] *and* **George P. Studzinski**[3, 4, 5]

ABSTRACT—Acid-soluble extracts of normal human fibroblasts (IMR 90 cells) exposed to [^{3}H]aminonucleoside of puromycin ([^{3}H]AMS) contained larger amounts of unchanged AMS than did similar extracts of their transformed counterparts (AG 2804 cells). The radioactive compounds present in IMR 90 cells were further analyzed by sequential high-voltage paper electrophoresis, enzyme digestion, and paper chromatography. In addition to unchanged [^{3}H]AMS, only [^{3}H]adenosine, [^{3}H]inosine, and [^{3}H]adenosine monophosphate could be detected, apparently derived from [^{3}H]adenosine present in the [^{3}H]AMS samples added to the cultures. Consistent with the absence of metabolism of AMS in IMR 90 cells was the failure to find AMS derivatives in the RNA or DNA of these cells. The content of ribonucleoside triphosphates (rNTPs) in acid-soluble extracts of IMR 90 cells was significantly reduced by AMS treatment, and nuclei or broken cell preparations obtained from AMS-treated IMR 90 cells incorporated [^{3}H]UTP into macromolecules at approximately control rates, when supplemented with rNTPs. These findings indicated that the reduced level of rNTPs may be responsible for the AMS-induced inhibition of RNA synthesis in normal cells.—JNCI 1982; 68:407–413.

The adenosine analog AMS has been shown to have markedly different effects on the nucleic acid metabolism and growth of various cultured normal and transformed mammalian cells (*1–7*). In normal cells AMS inhibits nonselectively the synthesis of all species of RNA and arrests the cell cycle traverse, principally in the G_1 phase. However, in fibroblasts transformed by an oncogenic virus, simian virus 40, AMS has a particularly marked inhibitory effect on ribosomal RNA synthesis but permits continued, though increasingly retarded, traverse of the cell cycle by the treated fibroblasts.

Our recent work has provided an explanation for the selective inhibition of ribosomal RNA synthesis in transformed cells (*8–10*). It appears that in these cells AMS is slowly demethylated, then sequentially phosphorylated to a triphosphate derivative, which can be incorporated by RNA polymerases into growing RNA chains, thereby causing premature termination of these chains. The severity of the effect on ribosomal RNA can be explained by structural changes in the nucleolus, which result from incorporation of demethylated AMS into preribosomal RNA and which greatly potentiate the biochemical effect (*10*). The explanation for the absence of such an effect on ribosomal RNA synthesis in normal cells was not available.

In this communication we present data indicating that AMS is not metabolized by the normal fibroblast and therefore cannot be incorporated into the RNA of the nucleolus. The inhibitory effects of this drug can be attributed to the reduction in the intracellular concentration of rNTPs for RNA synthesis.

MATERIALS AND METHODS

Materials.—The purine derivatives AMS, AMP, adenosine, adenine, N^6-monomethylaminopurine-9-riboside, and the enzymes nucleotide pyrophosphatase (EC 3.6.1.9), alkaline phosphatase from *Escherichia coli* (EC 3.1.3.1), deoxyribonuclease I (EC 3.1.4.5), and snake venom phosphodiesterase I (EC 3.1.4.1) were purchased from Sigma Chemical Co., St. Louis, Mo. N^6,N^6-Dimethylaminopurine-9-riboside was purchased from Vega Biochemicals, Tucson, Ariz. Nucleoside triphosphates were obtained from ICN Chemical and Radioisotope Division, Irvine, Calif. The [^{3}H]AMS was purchased from Amersham Corp., Arlington Heights, Ill. (10.6 Ci/mmol; general label). It was found to contain a small percentage of contaminating adenosine (*see* text-fig. 2), but attempts at further purification by electrophoresis resulted in the appearance of unidentified breakdown products. New England Nuclear Corp., Boston, Mass. supplied [5,6-^{3}H]uridine (38.8 Ci/mmol), [^{32}P]orthophosphate (carrier-free), and [5,6-^{3}H]UTP (46.3 Ci/mmol).

Cell culture.—Human lung fibroblasts (IMR 90 cells) and their simian virus 40-transformed derivatives (AG 2804 cells) were obtained from the Institute for Medical Research, Camden, N.J. The IMR 90 cells were grown as monolayers in 75-cm^2 plastic flasks (Corning Glass Works, Corning, N.Y.,) with the use of McCoy's 5-A medium supplemented with 20% fetal bovine serum (heat inactivated at 55°C for 30 min) and 1% glutamine. AG 2804 cells were grown in Corning flasks, and Eagle's minimum essential medium supplemented with 10% newborn calf serum (also heat inactivated) and 1% glutamine was used. Antibiotic supplements were not used for either cell line.

Preparation of PCA extracts for electrophoretic analysis.—Ten flasks of IMR 90 cells or four flasks of AG 2804 cells were exposed to 12.5 µCi of [^{3}H]AMS and 100 µg of unlabeled AMS/ml of McCoy's 5-A medium. Each flask was given 10 ml of the labeling medium. Following 18 hours of incubation at 37°C, the medium was removed and the cell sheets were rinsed four times with ice-cold 0.1 *M* sodium PBS (0.85% NaCl; pH 7.0). The cells were gently suspended in PBS with a rubber spatula and centrifuged at 800×*g* at 4°C for 10

ABBREVIATIONS USED: AMS=aminonucleoside of puromycin; DDT=1,4-dithiothreitol; PBS=phosphate-buffered saline; PCA=perchloric acid; PEI=polyethyleneimine; rNTPs=ribonucleoside triphosphates; TCA=trichloroacetic acid.

[5] We thank Ms. Marsha Trocola-Simchera for tissue culture preparations.

minutes. The cells were washed once by resuspension in PBS and centrifugation. The pellets were suspended in 2 ml of ice-cold distilled water and disrupted by 25 strokes in an 8-ml Potter-Elvehjem homogenizer (Kontes #22). Then 70% PCA was added to a final concentration of 5%. The homogenate was mixed in a vortex and kept on ice for 15 minutes before being centrifuged for 10 minutes at 800×*g*. The supernatant was saved, and the pellet washed two times with 2.5% ice-cold PCA and kept for further analysis. The supernatant and washes were combined, neutralized with KOH, and centrifuged at 2,900×*g* for 10 minutes. The final extract was lyophilized and stored for further analysis.

Determination of the incorporation of [^{3}H]AMS into nucleic acid.—Thirty flasks of IMR 90 cells were exposed to 333 μCi of [^{3}H]AMS with unlabeled 340 μ*M* AMS (100 μg/ml) in 10 ml of McCoy's 5-A medium per flask and incubated for 18 hours. PCA pellets obtained as described above were washed twice with 10 ml of 2.5% PCA and precipitated three times out of ice-cold 0.1 *N* NaOH with 10% PCA as previously described (*9*). The final pellet was hydrolyzed in 3 ml of 0.3 *N* KOH at 37°C for 24 hours. The hydrolysate was neutralized with PCA, centrifuged at 2,900×*g* for 10 minutes, and lyophilized. The remaining pellet, containing the DNA, was subjected to successive digestion with DNase I and snake venom phosphodiesterase I (*9*).

High-voltage electrophoresis.—The lyophilized samples were resuspended in 700 μl of distilled water and spotted across 5-cm-wide Whatman 3MM electrophoresis paper. The buffer contained pyridine, acetic acid, and water (1:10:89; pH 3.5). Electrophoresis was done on a Gilson model D high-voltage electrophorator for 1.5–3 hours at 2,000 V.

Elution of compounds from electrophoretic strips.—Sections of the paper strip (1 cm) were suspended over beakers of distilled water, and the compounds in the paper were allowed to concentrate at the tip of the paper by capillary action. The sections were then attached to the lip of a conical centrifuge tube with the tip of the paper pointing into the tube. The tubes were centrifuged at 300×*g*, and the water drawn out of the paper carried the compound into the tube. The eluted samples were lyophilized for further analysis.

Enzymatic digestion of compounds eluted from electrophoretic strips.—In the case of alkaline phosphatase, the lyophilized material was dissolved in 0.2 ml of 0.1 *M* Tris buffer (pH 8.0) and incubated at 37°C, with a total of 150 μg of enzyme added in 50-μg aliquots at 15-minute intervals. For nucleotide pyrophosphatase digestion the sample was dissolved in 0.2 ml of 0.02 *M* Tris buffer (pH 7.4) containing 1 m*M* $MgCl_2$. Then 0.01 U of the enzyme was added to the sample and incubated at 37°C for 15 minutes, after which all samples were stored at −20°C until electrophoresis could be performed.

Acid hydrolysis of compounds eluted from electrophoretic strips.—The lyophilized material was dissolved in 50 μl of 1 *N* HCl and heated at 100°C for 1 hour. The samples were chromatographed along with adenine and hydrolysates of N^6-methyladenosine and N^6,N^6-dimethyladenosine. The paper used was Whatman 3MM, and the solvent system contained isopropanol, NH_4OH, and H_2O (7:1:2; pH 11) (*9*).

Radioactivity measurements of electrophoretic strips and chromatograms.—Sections of paper (1 cm) were minced with scissors and placed in scintillation vials. Then 1 ml of water was added and the vials were heated at 60°C for 2 hours. The vials were mixed in a vortex for 30 seconds, Biofluor was added, and the vials were mixed in a vortex for another 30 seconds. The radioactivity was measured in an Intertechnique scintillation counter (model 4000).

Preparation of nuclei and cell homogenates.—Flasks of cells treated with 340 μ*M* AMS for varying periods of time were rinsed with PBS and harvested as described above. The washed pellet was suspended in buffer A [0.12 *M* Tris (pH 7.8), 0.02 *M* KCl, 0.01 *M* $MgCl_2$, and 0.3 *M* sucrose] and centrifuged at 800×*g* for 10 minutes. The cells were resuspended in buffer A and disrupted by 12 strokes in an 8-ml Potter-Elvehjem homogenizer. The homogenate was centrifuged at 800×*g* for 10 minutes and washed once in buffer A. The pellet was then suspended in buffer B [0.25 *M* sucrose, Tris (pH 7.5), 25 m*M* KCl, and 5 m*M* $MgCl_2$] and rehomogenized with 12 strokes. The crude nuclear suspension was placed over buffer C [1.1 *M* sucrose, 50 m*M* Tris (pH 7.5), 25 m*M* KCl, and 5 m*M* $MgCl_2$) and centrifuged at 2,900×*g* for 30 minutes. The final nuclear pellet was resuspended in buffer A containing 1 m*M* DTT.

In the case of cell homogenates, cell pellets, after being washed in PBS, were directly homogenized in buffer A with 1 m*M* DTT (12 strokes) and used in RNA polymerase assays.

Assays of RNA synthesis by isolated nuclei or cell homogenates.—The incubation mixture contained 50 μl of nuclei or cell homogenate (8–12 μg DNA), ATP, GTP, and CTP (all 0.6 m*M*), and 5 μCi [5,6-^{3}H]UTP. (Specific activity after addition of unlabeled UTP was 304 mCi/mmol.) The final volume was adjusted to 100 μl with distilled water. In some experiments cell homogenates were not exposed to exogenous unlabeled rNTPs, but only to 5 μCi of high specific activity [5,6-^{3}H]UTP (sp act, 46.3 Ci/mmol). The preparations were incubated at 37°C for indicated periods of time, the reaction was stopped by the addition of 1 ml ice-cold 10% TCA, and the precipitate was collected by centrifugation, dissolved in 0.1 *N* NaOH, and reprecipitated with 10% TCA. This procedure was repeated, and the final pellet was dissolved in 250 μl of 0.1 *N* NaOH mixed with 10 ml of Biofluor. Radioactivity was determined in the liquid scintillation counter.

Incorporation of [5,6-^{3}H]uridine into intact cells.—Cells were seeded in Costar six-well cluster dishes and exposed to 340 μ*M* AMS for varying periods of time. After incubation with the drug, the medium was removed and replaced with 1 ml of fresh medium without serum or AMS, containing [5,6-^{3}H]uridine (5 μCi/ml). One hour later the labeling medium was removed, the cells were rinsed three times with 1 ml of PBS, 500 μl of 5% TCA was added to the wells, and the dishes were kept at 4°C for 30 minutes. The TCA was then removed and the cell sheet washed two times with 1 ml of fresh 5% TCA. The final sample containing acid-precipitable material was dissolved in 500 μl of 0.1 *N* NaOH. A 250-μl aliquot of this solution was added to 10 ml of Biofluor, and the radioactivity was counted by liquid scintillation.

Measurement of relative concentrations of rNTPs.—IMR 90 cells, grown in 75-cm^2 plastic flasks, were incubated with 5 µCi [^{32}P]orthophosphate/ml in 9 ml of Dulbecco's medium supplemented with 20% fetal bovine serum and 1% glutamine. After 24 hours at 37°C, AMS was added in 1 ml of sterile water to a final concentration of 340 µ*M*. Control flasks received 1 ml of sterile water. The cells were incubated with AMS for 18 hours, the medium was removed, and the cells were rinsed and harvested with PBS as described above. The cell pellet was extracted with 500 µl of ice-cold 1 *M* formic acid. The mixture was mixed in a vortex at 15-minute intervals for 1 hour, then centrifuged at 2,900×*g* for 30 minutes. The supernatant was mixed with unlabeled standard triphosphates, and 5-µl aliquots were spotted on PEI cellulose thin-layer sheets. Chromatograms were developed with 0.85 *M* KH$_2$PO$_4$ (pH 3.4) (*11*). The spots were visualized by UV light, cut out, and added to vials with 3 ml of Biofluor, and the radioactivity was counted by liquid scintillation.

DNA measurement.—DNA content was measured by Fleck and Munro's (*12*) modification of the Schmidt-Thannhauser procedure (*13*).

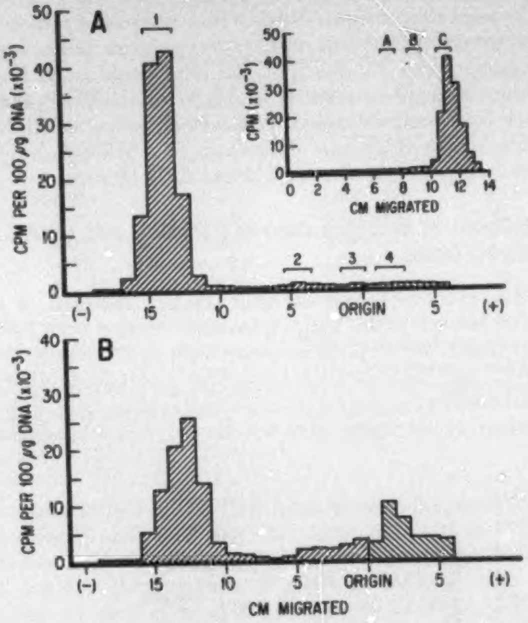
RESULTS

Analysis of Radioactive Compounds in the Acid-Soluble Extracts of Fibroblasts Treated With [^{3}H]-AMS

The IMR 90 fibroblasts were incubated with [^{3}H]AMS for 18 hours, and the PCA extract was analyzed by high-voltage electrophoresis (text-fig. 1A). The pattern of radioactive compounds thus obtained was compared with the pattern obtained for identically treated transformed fibroblasts (text-fig. 1B). In both cell lines, unchanged AMS was the principal radioactive compound, but the drug accumulated to a much greater extent in normal than in transformed cells. Conversely, smaller amounts of radioactive compounds other than AMS were present in extracts of normal cells.

We have previously established that in transformed cells AMS must be demethylated in the N^6 position before it can be further metabolized and incorporated into cellular RNA (*9*). Demethylated derivatives of AMS cannot be separated from the parent compounds by electrophoresis, but the separation can be easily accomplished by paper chromatography in appropriate solvents. Therefore, for the determination of whether area 1 of the electrophoretogram shown in text-figure 1A contained demethylated AMS (3′-amino-3′-deoxyadenosine) as well as unchanged AMS, this area was eluted, hydrolyzed with HCl to liberate the purine bases, and subjected to paper chromatography in a system that separates adenine from its methylated derivatives. As shown in the inset to text-figure 1A, area 1 contained only N^6,N^6-dimethyladenine, indicating that no detectable demethylation took place in the normal cells incubated with the drug for 18 hours.

Radioactive compounds found in the cells exposed to [^{3}H]AMS can be derived from this component and also from [^{3}H]adenosine, which contaminates the available [^{3}H]AMS preparations as shown in text-figure 2 (*9, 10*). The minor peaks in text-figure 1A, areas 2–4, were therefore eluted from the electrophoretograms and subjected to an analysis summarized in table 1. It is clear that these peaks represented contaminant [^{3}H]adenosine and its metabolites inosine and AMP. No metabolites of AMS could be detected in the intracellular pools of IMR 90 cells.



TEXT-FIGURE 1.—Electrophoretograms of the radioactive compounds in the PCA extracts of IMR 90 and AG 2804 cells after exposure to 12.5 µCi [^{3}H]AMS/ml and unlabeled AMS (340 µ*M*) for 18 hr. A) Acid-soluble extract of IMR 90 cells. Areas 1 through 4 were eluted for further analysis. *Inset* represents a chromatogram of the HCl hydrolysate of the material eluted from area 1. Adenine and acid hydrolysates of N^6-mono and N^6,N^6-dimethyl derivatives of adenosine were cochromatographed as standards and visualized by UV light. These standards are designated A, B, and C, respectively, in the *inset*. B) Acid-soluble extract of AG 2804 cells.

Absence of Incorporation of [^{3}H]AMS Into RNA in IMR 90 Cells

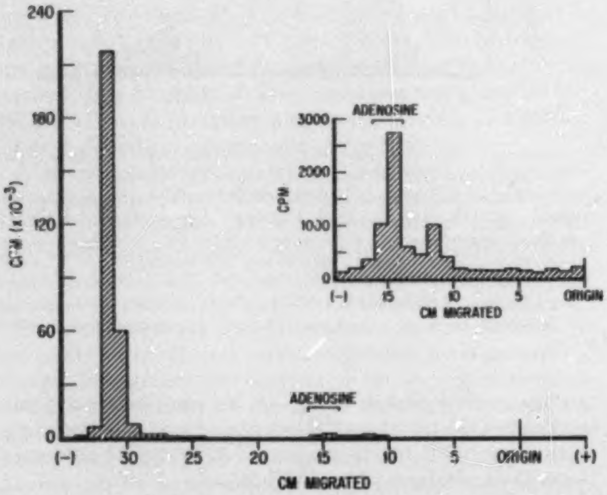
Preliminary experiments, performed according to protocols that demonstrated the incorporation of [^{3}H]3′-amino-3′-deoxyadenosine derived from [^{3}H]AMS into the RNA of transformed cells (*9, 10*), failed to show such incorporation into the RNA of IMR 90 cells. This observation is in keeping with the lack of conversion of AMS in these cells into phosphorylated metabolites that could form the substrates for RNA polymerases and was confirmed by the use of a larger number of cells (fourfold increase) exposed to a higher concentration of [^{3}H]AMS (fivefold increase).

Text-figure 3 shows that the alkaline hydrolysate of the residual pellet obtained after PCA precipitation and washes of IMR 90 cells exposed to [^{3}H]AMS contained only the radioactivity migrating with AMS. This radioactivity could be attributed to [^{3}H]AMS adsorbed to pellet contents by noncovalent bonds. Radioactivity derived from the [^{3}H]3′-amino-3′-deoxyadenosine intermediate, covalently incorporated into RNA, would migrate with AMS due to its ribose amino group, but acid hydrolysis would liberate adenine.

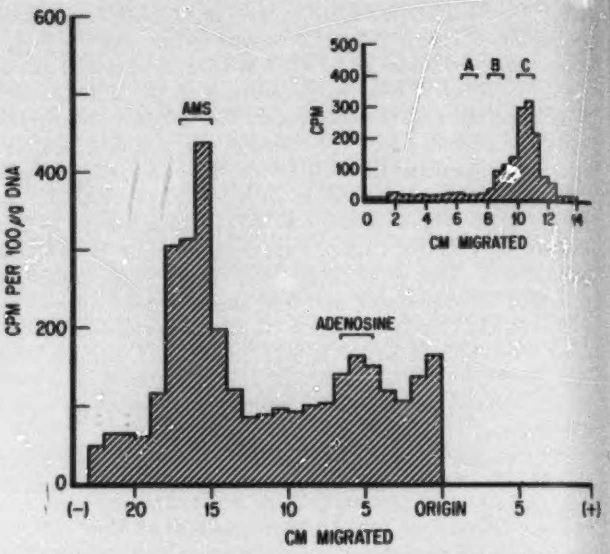
The inset to text-figure 3 shows that no peak of radioactivity was present in the area of the chromatogram migrating with adenine (area A) and that the only peak noted had the chromatographic mobility of N^6,N^6-dimethyladenine and, therefore, was presumably derived from adsorbed [^{3}H]AMS. Thus we conclude that demethylated AMS derivatives are not incorporated into the RNA of IMR 90 cells.

Absence of Incorporation of [^{3}H]AMS Into DNA of IMR 90 Cells

The material remaining after alkaline hydrolysis of PCA-extracted cell pellet was sequentially treated with DNase I and snake venom phosphodiesterase I as described in "Materials and Methods." Radioactive compounds migrating with AMS were not detected on high-voltage paper electrophoresis of the digest (data not shown), which indicates that AMS or a derivative is not incorporated into the DNA of IMR 90 cells treated for 18 hours with the drug.



TEXT-FIGURE 2.—Electrophoretogram of [^{3}H]AMS as received from the supplier. The sample contained 0.5 μCi [^{3}H]AMS and 100 μg of unlabeled AMS. *Inset* is an enlargement of area showing the minor peak that migrated with standard adenosine.



TEXT-FIGURE 3.—Electrophoretogram of the KOH hydrolysate of the PCA pellet obtained from 30 flasks of IMR 90 cells exposed for 18 hr to 33.3 μCi [^{3}H]AMS/ml; unlabeled AMS was added to 340 μM. Unlabeled AMS and adenosine were coelectrophoresed as markers and visualized by UV light *Inset* represents a chromatogram of the HCl hydrolysate of the material eluted from the area migrating with the marker AMS. Adenine and acid hydrolysates of N^6-mono and N^6,N^6-dimethyl derivatives of adenosine were cochromatographed as standards and visualized by UV light. These standards are designated A, B, and C, respectively, in the *inset*.

Comparison of the Inhibitory Effect of AMS on RNA Synthesis in Nuclei Isolated From IMR 90 Cells, in Cell Homogenates, and in Intact Cells

The absence of any evidence of metabolism of AMS or its incorporation into RNA of IMR 90 cells raised the question as to the mechanism of the inhibition of growth and nucleic acid synthesis that this drug induces in normal fibroblasts

TABLE 1.—*Summary of the analyses performed on PCA extract of IMR 90 cells incubated for 18 hours with [^{3}H]AMS*

Area of electrophoretic strip	Electrophoresis[a]	Paper chromatography[b]	Paper chromatography after HCl digest	Electrophoresis after alkaline phosphatase treatment	Electrophoresis after pyrophosphatase treatment	Compound identified as:
1	Migrated with standard AMS	Cochromatographed with standard AMS	Cochromatographed with N^6,N^6-dimethyladenine	Not applicable	Not applicable	AMS
2	Migrated with standard adenosine	Cochromatographed with standard adenosine	Cochromatographed with standard adenine	Not applicable	Not applicable	Adenosine

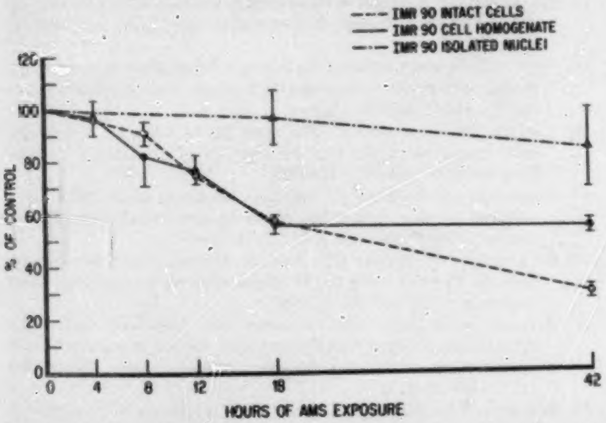
[a] As described in "Materials and Methods."

[b] A small amount of conversion to adenosine was noted, which was due to a slight phosphomonoesterase activity in the nucleotide pyrophosphatase preparation reported by the supplier.

(3–5). A clue to the basis of the inhibitory effect of AMS on RNA synthesis was obtained by a comparison of the results obtained when AMS inhibition of RNA synthesis was measured by different methods (text-fig. 4). The inhibition of RNA synthesis became apparent after 4 hours of AMS treatment when determined by incorporation of uridine into acid-insoluble material of intact cells. That this was not due to a cell membrane effect on cellular uptake of uridine is shown by the almost identical results obtained when UTP was incorporated into the RNA of mechanically disrupted cells.

In contrast, measurement of UTP incorporation into the RNA of nuclei isolated from AMS-treated IMR 90 cells showed no effect of AMS during the first 18 hours of AMS treatment and only a minor depression of RNA synthesis thereafter. A possible explanation for the lack of the inhibitory effect of AMS as determined in isolated nuclei could be that RNA synthesis in isolated nuclei is measured in the presence of exogenously supplied rNTPs, whereas the incorporation of an RNA precursor in intact cells or homogenates depends on the presence of endogenous substrates. The possibility that the level of ATP or other rNTPs limited the rate of RNA synthesis in AMS-treated IMR 90 cells and homogenates was tested by supplementation of cell homogenates with such exogenous substrates. The data in table 2 show that addition of rNTPs to homogenates prepared from AMS-treated cells abolishes the effect of AMS on RNA synthesis in these homogenates. These results suggest that AMS inhibits the synthesis of RNA in IMR 90 cells by reducing the pool of available substrates for RNA polymerase action.



TEXT-FIGURE 4.—Time course of the effect of AMS (340 *μM*) on the RNA synthesis in IMR 90 cells as measured by incorporation of [5,6-^{3}H]uridine in intact cells (○- - -○), incorporation of [5,6-^{3}H]UTP in cell homogenates (●—●), and incorporation of [5,6-^{3}H]UTP in isolated nuclei supplemented with exogenous rNTPs (△-·-·-△). Incubation time with the radiolabel for cell homogenates and isolated nuclei was 2 min; for intact cells, it was 60 min. Other incubation conditions are described in "Materials and Methods."

TABLE 3—*Effect of AMS (340 μM for 18 hr) on the rNTPs pools of IMR 90 cells*[a]

Expt No.	rNTPs	[^{32}P]orthophosphate/10 μg DNA		Control, %
		Control, mean ± SD	AMS-treated, mean ± SD	
1[b]	GTP	2,480±490	1,879±218	75.8

[c] *n*=6.

Effect of AMS on the Intracellular Content of rNTPs

Levels of rNTPs were measured in IMR 90 cells allowed to equilibrate with [^{32}P]orthophosphate for 24 hours and then treated with AMS for 18 hours in the presence of [^{32}P]orthophosphate. The results shown in table 3 indicate that the levels of rNTPs were reduced by AMS to a moderate degree. Unexpectedly, pyrimidine rNTPs as well as the purine rNTPs were lowered by the treatment, though the reduction in UTP concentration was less marked than the reduction in the concentration of other rNTPs. These data strengthen the view that the inhibition of RNA synthesis seen in IMR 90 cells after prolonged treatment with AMS is mediated by a reduction in the cellular content of rNTPs.

Similar measurements of rNTP levels in AG 2804 cells showed that treatment with AMS for 18 hours also caused a drop in the pools of rNTPs (table 4), which may contribute to the more delayed effects of AMS on these cells.

DISCUSSION

The essential difference between the normal and transformed cell response to AMS seems to be the low ability of

TABLE 2.—*Effect on the incorporation of [^{3}H]UTP into RNA of the addition of rNTPs to homogenates of IMR 90 cells treated with AMS*[a]

Time of incubation with [^{3}H]UTP, min	Experimental group	Incubation with [^{3}H]UTP only		Incubation with [^{3}H]UTP + rNTPs

CTP	2,319±331	1,946±216	83.9
UTP	4,801±509	3,826±238	79.7

[a] AG 2804 cells were exposed to 5 μCi [^{32}P]orthophosphate/ml for 24 hr and then to 340 μ*M* AMS and 5 μCi [^{32}P]orthophosphate/ml for 18 hr (total of 42 hr of incubation with [^{32}P]orthophosphate). Formic acid extract was analyzed for rNTPs by PEI anion-exchange chromatography as described in "Materials and Methods." The means and SD are for six determinations.

the normal cells to metabolize AMS. This low ability may explain the observed greater accumulation of nonmetabolized AMS in the acid-soluble pools of normal fibroblasts when compared to its accumulation in transformed fibroblasts, though the greater rate of uptake of this compound by normal fibroblasts may have contributed to this effect (*14*). Evidence that the accumulated AMS is not appreciably metabolized by normal cells was difficult to gather because it was not possible in these studies to obtain (or completely purify) [^{3}H]AMS samples totally free of the small amounts of [^{3}H]adenosine. However, it was possible to obtain such evidence mainly because the 3′-amino group in AMS is highly charged and thus confers high electrophoretic mobility to AMS and all its metabolites, and there is no known mechanism for removing this amino group from the sugar molecule.

Special efforts were also made to ensure detection of small amounts of AMS metabolites that could perhaps be incorporated into cellular RNA. Nonetheless, in spite of increasing the amounts of [^{3}H]AMS and of cell cultures used for these studies, to the point that less than 1% of the transformed cell rate of AMS incorporation into RNA would have been detected if it also occurred in the normal fibroblasts, we were unable to find any incorporation. We conclude, therefore, that if incorporation of AMS into RNA occurs in normal fibroblasts, it is insignificant when compared to the amount incorporated by transformed fibroblasts.

Data presented here also indicate that treatment with AMS reduces the levels of ribonucleoside triphosphate precursors in normal and transformed fibroblasts, and this reduction may be responsible for the gradual onset of inhibition of RNA synthesis brought about in normal cells by this treatment. This effect may also be a secondary cause of the inhibition by AMS of the growth of the transformed fibroblasts. A similar sequence of events has been reported for histidine-starved Ehrlich ascites cells, in which purine nucleoside triphosphate pools shrank to about 70% and nucleolar RNA synthesis was reduced to about 40% of the control value (*15*). The importance of changes in purine precursor pool levels to the mechanism of AMS action in these cells is also suggested by the observations that the inhibitory or differentiation-inducing effects of AMS can be blocked by simultaneous addition of equimolar inosine (*3*, *16*) and that cordycepin, a compound with great structural similarity to AMS (*17*), may exert its inhibitory effect by interfering with the de novo biosynthesis of purines, thus causing a depletion of the cellular adenine nucleotide pools (*18–20*), though this compound can also cause premature termination of RNA chains (*21*, *22*). However, purine analogs which have a 3′-hydroxyl group and are incorporated into RNA have been shown to interfere with its maturation (*23*).

In view of these results, we conclude that the altered cellular responses to AMS that are seen after simian virus 40 transformation stem from the greatly enhanced ability of the transformed cells to remove the methyl groups from the N^6 position of AMS, probably due to the increased activity of demethylating or transmethylating enzymes. This ability leads to the phosphorylation and incorporation of AMS metabolites into RNA of transformed cells, where additional effects occur in the nucleolus (*10*). The mechanism through which AMS causes a reduction in the levels of pools of rNTPs, presumably by the unchanged drug, remains to be elucidated.

Phenotypic and Genotypic Characteristics of a Cell Line From a Squamous Cell Carcinoma of Human Skin[1,2]

Petra Boukamp,[3] Wolfgang Tilgen,[4] Rule T. Dzarlieva,[3] Dirk Breitkreutz,[3] Dietrich Haag,[5] Rüdiger K. Riehl,[4] Axel Bohnert,[3] *and* Norbert E. Fusenig[3,6,7]

ABSTRACT—A human cell line (SCL-1) from a poorly differentiating cutaneous squamous cell carcinoma (SCC) was studied through 20 passages during 2 years. Cells maintained their original morphology with low degree of keratinization, as indicated by light and electron microscopy. The keratin peptide pattern resembled the type in SCC tumors, and the corresponding filaments were detected by immunofluorescence at all passage levels. Cells did not grow in soft agar but formed tumor-like nodules in an "organotypic" culture assay (on lifted collagen gels) and grew invasively after transplantation to immunosuppressed inbred C3H mice. After injection into BALB/c *nu/nu* mice, tumors of SCC morphology were formed. The hypodiploid tumor stemline was maintained for about 10 passages, when a shift to hyperploidy started, as determined by chromosome and DNA flow microfluorometric analyses. Two stable marker chromosomes (in 100 and 70% of the metaphases, respectively), involving chromosomes 7 and 9, strongly indicated a monoclonal origin of this cell line.—JNCI 1982; 68:415–427.

The availability of cell lines from various carcinomas with well-defined morphology, cytogenetics, and biologic behavior will greatly facilitate in vitro studies of the properties of malignant human epithelial cells, as well as studies of their sensitivity or resistance to radiation and chemotherapy. Investigations with several cell lines derived from individual tumors of the same type and tissue may clarify problems concerning the similarities and heterogeneity of tumor cells from the same tissue.

Although tissue culture models offer considerable advantages in the study of normal and tumor cells, the likeness of long-term-cultured cells to cells of the original normal or tumor tissue has rarely been substantiated. Due to selection for the most efficiently attaching and proliferating cells in primary culture and at each passage level, the original tumor cell population may have been considerably changed. Further alterations may occur within the cultivated cell population due to growth conditions in vitro. Thus preparations from tumor biopsies have to be compared with primary, early- and late-passage cultures to discriminate characteristics associated with the predominant tumor cell population in vivo from those that are merely consequences of culture conditions.

Since the first human epithelial cell line HeLa was established by Gey in 1951 (*1*), many carcinoma cell lines from different human organs have been characterized with respect to their tissue specificity and malignancy (*2–7*). It is still rather difficult to establish defined human epithelial tumor lines, as evidenced by the low success rate of 1–38%, probably due mainly to the low tendency of epithelial cells to grow in vitro. Most of the successful attempts started with cells from metastases, effusions, or ascitic fluids, and those cells might have acquired growth abilities different from those of cells of the primary tumor (*5, 8–13*). To our knowledge, no report has characterized in detail a cell line derived from a primary SCC of the skin.

In this paper, we report the development of a human epithelial cell line (SCL-1) derived from biopsy material of a cutaneous SCC. The studies include the analysis of cell growth and morphology, neoplastic behavior in vivo and in vitro, the determination of differentiation functions such as keratin polypeptides and cytoskeleton pattern, and the cytogenetic and cytometric analyses of the cell populations. The SCC cells were studied in explant cultures and through the first 20 passages over a period of 2 years.

MATERIALS AND METHODS

Culture medium.—A modified Eagle's minimum essential medium (four times the concentrated ingredients) (*14*) with 17% fetal calf serum was used throughout. All medium components were obtained from Seromed (Munich, FRG). Penicillin (100 U/ml), streptomycin (50 µg/ml), and ampicillin (50 µg/ml) were added. Dulbecco's PBS and EDTA were obtained from Serva (Heidelberg, FRG), and trypsin (1:250) came from Boehringer (Mannheim, FRG).

Culture conditions.—A poorly differentiated solid SCC of the face from a 74-year-old woman was removed surgically and immediately prepared for tissue culture, electron microscopy, and cytometry. At surgery no metastases were observed. The biopsy material was rinsed several times in complete growth medium with antibiotics, freed of necrotic or surrounding connective tissue, and cut with scalpels into cubes of about 2-mm diameter. Then 6–8 of these specimens were placed individually in 35-mm plastic petri dishes (Fal-

con Plastics, Oxnard, Calif.), covered by a plasma clot (Difco Laboratories, Detroit, Mich.), and left for 30 minutes at room temperature, after which 2 ml of complete culture medium was added. The dishes were then incubated at 37°C in a humidified atmosphere of 5% CO_2 in air. Medium was changed once a week. Cultures were examined and photographed under an inverted microscope with the use of phase-contrast optics (Wild Heerbrugg Instruments Inc., Heerbrugg, Switzerland). Fibroblasts that usually would grow at the periphery of the outgrowing epithelial sheet were eliminated with brief trypsin treatment (0.25% at 37°C for 1–2 min).

For generation of subcultures, the cells were rinsed in EDTA (0.2% for 2 min), incubated in EDTA–trypsin (5–7 min; final concentration), and flushed by pipette. Cells were enumerated in an electronic counter (Coulter Electronics Inc., Boulder, Colo.) and replated at high densities (5×10^5/cm^2). At different cell passage levels, growth curves were established by daily cell counts of duplicate dishes. Cloning efficiency was determined by plating 10^3 cells per 60-mm dish with or without conditioned medium (from confluent SCL-1 culture).

Three-dimensional growth behavior was tested of cells from different passages by plating 2×10^5 cells on collagen gels prepared in silicon chambers ("organotypic" culture assay) (*15, 16*). After cell attachment, the collagen layer was lifted to the medium–air interphase [with the use of "Stanzen" dishes (*15*)] while the medium covering the cells was drained. Thus cultures were nourished only from below by diffusion through the collagen, and the upper cell surface was exposed to air. For histologic examination, these organotypic cultures were fixed at weekly intervals in buffered Formalin and cross sections of paraffin-embedded specimens were stained with H & E or Masson-Goldner.

Anchorage-independent growth was examined in 0.3% soft agar on top of a 0.5% agar base (*17*). The agar (Bacto; Difco Laboratories) was prepared in complete culture medium with 17% fetal calf serum (final concentration); 10^4, 10^5, and 10^6 cells were plated in 60-mm dishes. Dishes were examined weekly, finally stained with 2-(*p*-iodophenyl)-3-*p*-nitrophenyl-5-phenyltetrazolium chloride (*18*) to detect viable colonies, and inspected under low-magnification optics.

Cultures from passage 17 were monitored for mycoplasma by inoculation in agar and broth and were found free of contamination.

Electron microscopy.—Electron microscopy was performed on the original tumor biopsy specimen and on intact cultures growing on plastic or collagen, as well as on the tumors induced in nude mice. Specimens from tumor material were prepared according to the technique of Peracchia and Mittler (*19*). Cells grown on plastic petri dishes were processed as described in (*20*). Ultrathin sections of an Epon-embedded specimen were stained with uranyl acetate and examined with a Zeiss electron microscope EM 109 or a Philips electron microscope, EM 400.

Extraction of cytoskeletal (keratin) proteins.—Confluent cell cultures were sequentially treated with isotonic buffer containing 0.5–1% Triton X-100 followed by high-salt buffer (1.5 *M* KCl) as described earlier (*16, 21, 22*). The remaining cytoskeletons were rinsed with isotonic buffer and extracted with 5% SDS, 10% mercaptoethanol, and 2 m*M* EDTA in 20 m*M* phosphate buffer (pH 7.2). The suspensions were heated at 100°C for 5 minutes, homogenized, and (after 30-60 min) centrifuged at $20{,}000\times g$ for 20 minutes to remove the insoluble material. For the preparation of total cellular proteins, culture dishes were rinsed extensively with PBS and extracted with SDS and mercaptoethanol as above. Corresponding preparations from frozen tumor tissue (stored in liquid nitrogen) were obtained by homogenization either in Triton X-100-containing buffers (isotonic and high salt) at 4°C followed by extraction ("cytoskeletal proteins") or directly in extraction buffers ("total proteins") as outlined above. To all buffers, fresh 0.1–1 m*M* phenylmethylsulfonyl fluoride was added before use.

Gel electrophoresis.—Proteins were analyzed by electrophoresis on slab gels in the presence of SDS according to the methods of Weber and Osborn (*23*) and Laemmli (*24*). Samples were heated at 100°C for 1 minute and applied to 10% acrylamide gels. Bromphenol blue was used as a tracking dye. Gels were stained with 0.05% Coomassie blue in 25% isopropanol and 7.5% acetic acid and destained with 7.5% acetic acid.

Indirect immunofluorescence test.—The intracellular distribution of the cytoskeletal network was visualized by the use of specific antibodies. Cells were grown on glass cover slips, washed in PBS, air dried, and fixed in acetone for 15 minutes at room temperature. The hydrated cover slips were first incubated for 45 minutes at 30°C with a guinea pig anti-bovine keratin antiserum (*20*) and thereafter with fluorescein-labeled goat anti-guinea pig IgG (Miles-Yeda, Rehovot, Israel). The cover slips were rinsed in PBS and Tris-HCl buffer (pH 8.5), mounted in Aqua-Mount (Lerner Laboratories, Stamford, Conn.), and examined with an inverted microscope with fluorescence optics (IM 35; Carl Zeiss, Inc., Oberkochen, FRG).

Tumorigenicity test.—We tested tumorigenicity in vivo by injecting 1×10^6 and 4×10^6 cells, respectively, im or sc into 7-week-old *nu/nu* mice (BALB/c and NMRI back-crosses). The animals were killed after about 3 months and the tumor material was taken for histology and biochemical analysis.

Invasive growth was tested in a transplantation assay with 2×10^5 cells implanted in 200 μl medium onto an induced subcutaneous graft bed (*15, 25*) in thymectomized and irradiated (400 rad) adult inbred C3H mice. Animals were killed after 7, 14, and 21 days, and the transplants were processed for routine histology. Serial sections were cut and stained with H & E, Masson-Goldner, and periodic acid–Schiff.

Cytogenetic studies.—Chromosome analysis was performed on cultures as soon as adequate growth was achieved (passage 2) and at regular intervals at subsequent passages. The cells arrested at metaphase with Colcemid (10^{-7} *M* for 2 hr) were harvested by EDTA–trypsin treatment (5 min) and processed according to the technique of Moorehead et al. (*26*).

For chromosome identification, G-banded preparations were made according to the method of Seabright (*27*). Slides, bearing good metaphase spreads, were allowed to age in the dark 2–3 weeks and then treated with 0.025% trypsin for 20–45 seconds and stained with 3% Giemsa in Sörensen's buffer (pH 6.8) for 12 minutes. Staining of centromeric heterochromatin (C-bands) was achieved according to methods reported by Sumner (*28*). Slides were examined on an Ortholux microscope (E. Leitz, Inc., Wetzlar, FRG). At least 50 G-banded metaphases were analyzed per passage.

Cytometric DNA determination.—DNA distribution patterns were determined in biopsy material and cultured cells by FMF and single cell analyses. Tumor tissues were prepared and stained according to the procedure of Zante et al. (*29*). The FMF–DNA histograms were evaluated as described (*30*). Cell cultures were trypsinized, filtered through 70-µm mesh, and centrifuged at 100×*g*; cells were stained in a solution of homidium bromide and 4′-6-diamidino-2-phenylindole or aureolic acid in 0.1 *M* Tris buffer (pH 7.6). DNA measurement was performed with an ICP 22 pulse cytophotometer (Phywe AG, Göttingen, FRG). Pulse height analysis was displayed with a multichannel analyzer (MCA 8100; Canberra Industries, Meriden, Conn.). Cell compartments were calculated according to their DNA content from up to 100,000 counts.

Single cell DNA measurements were performed on smears of cell suspensions from biopsies or on intact cultures after fixation in 95% ethanol and staining by the acriflavine–Feulgen procedure according to Prenna and Bianchi (*31*). Preparations were measured by light absorbance and fluorescence with the use of a scanning microspectrophotometer and a microscope fluorescence photometer (UMSP I and MPM; Carl Zeiss, Inc.). We determined ploidy stages by measuring at least 100 individual cell nuclei.

RESULTS

Development of the Cell Line

In SCC explant cultures epithelial outgrowth was first visible within 3–5 days. The cell sheets, composed of cuboidal, densely packed epithelial cells, continuously enlarged (fig. 1A), but a nearly complete monolayer was observed only after about 4 months. Then cells could be subcultured, but proliferation was low in early and later subcultures and was dependent on high cell density. During the first four passages, cultures reached confluence after about 2 months, whereas later (starting from passage 13) cells could be subcultured every 3 weeks. The mean population doubling time decreased from 6 days to about 60 hours (table 1), whereas the attachment rate stayed constant at 60% when determined 24 hours after plating. Growth at clonal or low cell density was not achieved until passage 18 and even then strictly depended on the addition of conditioned medium from SCL-1 cultures. Cloning efficiency was 6–10% in conditioned medium as compared to less than 1% in unconditioned medium.

Morphologic Characteristics of Cultured Cells

Explant cultures were composed of rather uniform, small polygonal cells with large nuclei and prominent nucleoli. Mitotic figures, sometimes with abnormal configurations were frequent (fig. 1B).

Subcultures were more heterogeneous, revealing two types of cell colonies with clearly different morphologies. Colonies of tightly packed, uniform polygonal cells (fig. 2A) alternated with defined areas of smaller cells exhibiting wider intercellular spaces (fig. 2B). This type of smaller cells eventually started to pile up and formed large nodules of proliferating cells (figs. 2C, D). Occasionally, some regions revealed the striated appearance typical for the differentiating upper layers of normal (mouse) keratinocytes (fig. 2C) (*14, 32*). Large and often multinucleated cells between the compact cell islands were frequent in all cultures (fig. 2B).

Ultrastructurally, SCL-1 cells could be identified as epidermal by their desmosomes and tonofilament bundles. Tonofilament bundles appeared less dense and more evenly distributed in later passage cultures (fig. 3) as compared to explant cultures. Cell and nuclear polymorphism with large, often indented nuclei was similar to that observed in the original tumor (fig. 4A), which was diagnosed as poorly differentiated with numerous atypical mitoses and few individual keratinized (dyskeratotic) cells (fig. 4B). The cytoplasmic organelles were well developed and microvilli were prominent at the cell borders.

Differentiation in Culture

Typical keratinization, including stratification and formation of continuous horny layers, was not observed in cultures of SCL-1 cells but keratinized cells with keratohyalin granules could be identified in explant cultures and subcultures. Occasionally, flat translucent cells with thickened membranes and pyknotic nuclei—resembling parakeratotic cells—were seen on top of the monolayers. These cells eventually detached and their "cornified envelopes" (*33*) could be identified by the insolubility in SDS. When grown on lifted collagen layers (organotypic culture assay), SCL-1 cells formed three-dimensional nodules, sometimes with central necroses or horn pearl-like structures (fig. 5A) but with no features of normal epidermal differentiation as observed with normal mouse keratinocytes (*34*). Unlike confluent cultures on plastic, cells could be grown on collagen for up to 3 months without detaching from the substrate. The ultrastructure of these nodules revealed only few dyskeratotic cells but wide intercellular spaces, often filled with long villous projections interdigitating with adjacent cells, and numerous mitoses were conspicuous (fig. 5B).

The cytoskeletal filaments of the cultured cells were com-

TABLE 1.—*Growth behavior of SCL-1 cells in vitro and in vivo, depending on passage number*[a]

[b] In medium conditioned on SCL-1 cultures.

posed of keratin proteins (tonofilaments), as also demonstrated earlier by immunologic and biochemical methods with keratinocytes from other species including humans (*20, 22, 35, 36*). In the indirect immunofluorescence test, antibodies against bovine keratin decorated a three-dimensional meshwork of fibers in SCL-1 cells (fig. 6). In early passages heavily labeled filaments were located especially around the nucleus, and numerous correspondences in adjacent cells indicated an extended filamentous system linked by desmosomal junctions. In later culture passages, fluorescence labeling of cytoskeletal filaments appeared weaker, corresponding to the ultrastructural observations. However, this finding might be due to an altered distribution of keratin fibrils rather than to a decrease in keratin content, as indicated by biochemical analysis.

The cystoskeletal proteins of SCL-1 cells were composed mainly of two strong and four somewhat less prominent peptide bands (size range, 45,000–59,000 daltons) in addition to some residual actin (fig. 7). The larger peptides (≥60,000 daltons) present in whole normal epidermis were virtually absent in both tumor tissue and SCL-1 cell cultures, a feature that might be common to most neoplastic lesions of the skin (*37, 38*). Qualitatively, the typical keratin pattern of SCC cells remained unchanged in culture when cells from passages 8 and 19 were compared. There was a striking similarity between the keratins in SCL-1 cultures and keratins in the original SCC tumor. The keratin protein pattern of the tumors formed after injection of SCL-1 cells in the nude mouse (fig. 7) resembled even more closely that of the primary tumor biopsy specimen than the pattern from cultured cells (data not shown).

Cytogenetic Characteristics

Chromosome analysis of SCL-1 cells, first done on second passage cultures 6 months after plating, revealed a heterogeneous (female) karyotype with a main hypodiploid stemline of 45 chromosomes. The G-banded karyotype showed monosomy for chromosomes 7, 9, and 15 and two metacentric marker chromosomes (fig. 8). The larger marker chromosome (M1) was derived from the long arms of chromosomes 7 and 9 (7q9q), and the smaller one (M2) was derived from the short arms of the same chromosomes (7p9p). These marker chromosomes were present at each passage level in 100% and 60–70%, respectively (table 2). No marker chromosome characteristic for HeLa cells or other similarities to the HeLa karyotype were found. Starting with passage 11, a side stemline with additional monosomy for chromosome 4 and trisomy for chromosome 20 appeared. Structural chromosome aberrations, including chromatid and chromosome breaks, fragments, minutes, and exchange figures, drastically increased with culture time, and additional marker chromosomes appeared mainly involving chromosomes 1 and 4.

The hypodiploid stemline as well as the hypotetraploid fraction stayed relatively stable up to passage 11, whereas the hypertetraploid fraction increased constantly and the level of endoreduplication diminished (table 3). With higher passages, however, the modal chromosome number increased to hypotetraploidy (73–90) and near-diploid cells had disappeared. Giant metaphases were observed only at later passages (20–30).

TABLE 2.—*Structural chromosome aberrations in the SCL-1 cell line*

Type of chromosome aberration	Percent of chromosome aberration in cell line at passage No.:

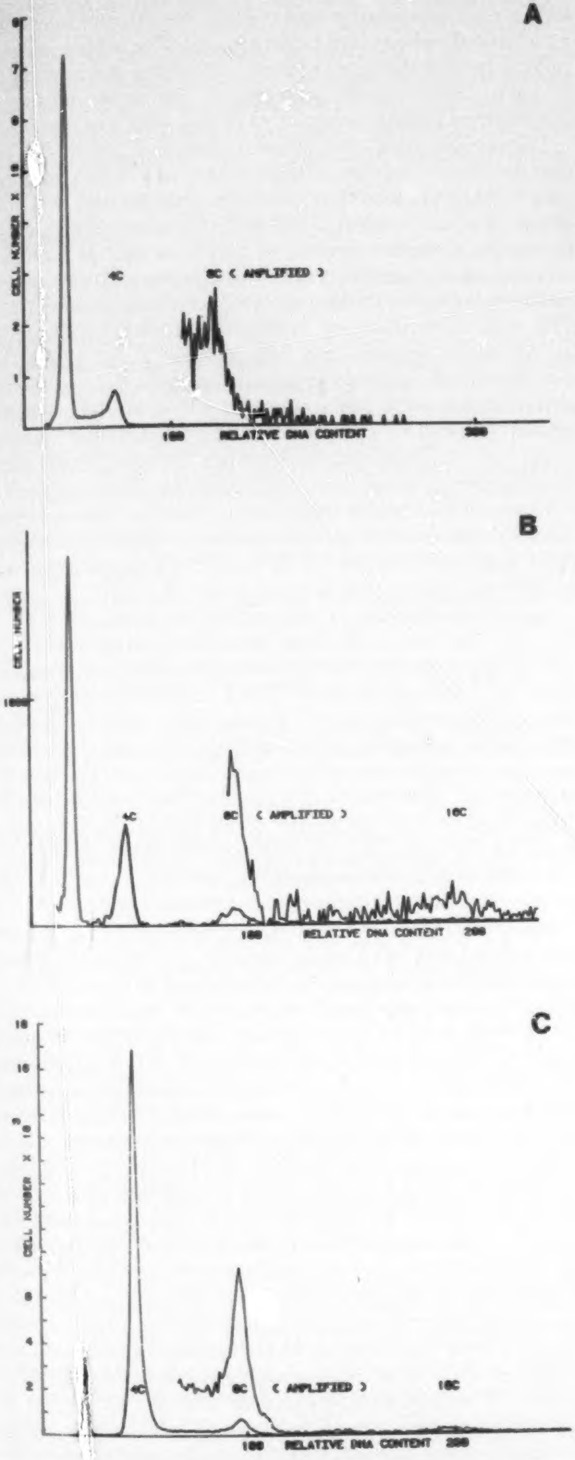
Cytometric DNA Analysis

In addition to chromosome analysis, quantitative DNA determinations such as those provided by pulse cytometry (FMF) or single-cell DNA measurement represent further means to follow-up changes in cell populations as far as stemlines and ploidy degrees are concerned. Moreover, data obtained by these methods provide information about the proliferative activity of cell populations (S-phase fractions).

The data show that the main tumor cell population in vivo was approximately diploid (2c) in its DNA content. Only a minor proportion of cells had a DNA content higher than 4c (text—fig. 1; table 4). Cells from 8-day-old explant cultures as well as from early passages (up to passage 10) revealed a similar DNA distribution pattern. However, in culture, the percentage of cells with an 8c DNA content had increased. Starting with passage 13, the population shifted toward a 4c DNA content, paralleled by a decrease in near-diploid (2c) cells. By passage 23, virtually all cells with a 2c DNA content had disappeared.

Thus both cytometric and cytogenetic analyses demonstrated that the original near-diploid tumor stemline was stable for up to 1.5 years or about 12 passages in culture and then shifted to a near-tetraploid level. The proportion of cells with higher ploidy levels stayed relatively un-



TEXT-FIGURE 1.—DNA distribution pattern determined by flow microfluorometric analysis. A) Primary tumor biopsy material with predominantly 2c DNA content (tumor stemline). B) Early passage (9) of SCL-1 with a similar DNA distribution. C) Later passage (16) of SCL-1 showing a predominant stemline with 4c DNA content.

TABLE 4.—*DNA histograms of human cutaneous SCC cells in primary and long-term cultures*

Source of cells	Percent of cells with relative DNA content:				
	2c[a]	4c	8c	16c	S-phase[b]
Tumor biopsy	76.5	13.0	1.0	0.0	9.5
Explant culture	38.0	38.0	11.5	0.5	12.0
Passage 7	55.0	27.0	7.5	2.5	8.0
Passage 13	30.0	53.0	5.0	0.0	12.0
Passage 16	6.0	81.0	4.0	1.0	8.0
Passage 23	0.0	83.0	8.0	0.0	9.0

[a] Human lymphocytes were used as standards and were located in the 2c region.

[b] Represents the sum of all fractions, positioned between the peaks of 2c, 4c, 8c, and 16c, i.e., both the cells in true S-phase and the heteroploid cells.

changed. Single cell measurements of Feulgen-stained cultures revealed a comparable DNA distribution pattern.

Malignant Growth Characteristics

Heterogeneous cell morphology, atypical mitoses, and the variations in DNA histogram and karyotype were strong indications of the transformed state of the SCL-1 cells. The low growth rate and the nearly normal (diploid) DNA content of cells in explant and early subcultures, however, were not typical for malignant cells. Moreover, SCL-1 cells up to passage 20 did not easily grow at clonal densities nor did they form colonies in soft agar (table 1). The addition of conditioned medium to the agar overlay did not stimulate colony growth, although it improved single cell cloning on solid substrate.

While the agar test failed to identify the transformed state of SCL-1 cells (i.e., anchorage independency), the growth behavior in the organotypic culture assay (described in "Materials and Methods") was abnormal and comparable to that of transformed mouse epidermal cells (*15, 16*). Cross sections from 1- to 3-week-old cultures showed actively proliferating nodules (fig.. 5) resembling ultrastructurally the primary tumor biopsy specimen.

Malignancy of SCL-1 cells could clearly be demonstrated at later passages in nude mice. Tumors developed after a long latency period of about 2 months when cells were injected (sc or im) into 7-week-old (BALB/c) *nu/nu* mice (table 1). We reduced the latency period, however, by using newborn animals (NMRI *nu/nu*). Histologically, the solid encapsulated tumors were SCC with a low degree of differentiation quite similar to that of the original SCC (fig. 9 cf. to fig. 4B).

Invasive growth behavior could already be demonstrated with SCL-1 cells from passage 5 when the available cell number was still insufficient for the nude mouse test (*15, 16, 39, 40*). When transplanted onto induced granulation tissue in immunosuppressed adult C3H mice, multilayered and invasively growing cell masses developed in 100% of the animals. Histologically, these tumor masses revealed features of the original tumor such as atypical mitoses, dyskeratotic cells, and giant cells (fig. 10). Invasiveness was clearly visible 1-3 weeks after transplantation of 2×10^5 cells. However, at the start of week 3, rejection of the transplants commenced.

Preliminary experiments demonstrated that the transplantation assay is also feasible with nude mice and may thus provide a more sensitive in vivo test for the study of invasion and metastasis of human tumor cells.

DISCUSSION

We have previously demonstrated by morphologic and biochemical criteria and by cell kinetics that the predominant cell population from cutaneous epithelial tumors can be propagated in explant cultures (*41, 42*). Here we describe the long-term cultivation of cells from an SCC from human skin obtained by a routine explant culture technique. Serial subcultures were achieved only by high seeding density, and cell growth could be improved by conditioned medium (from SCC cultures). A second cell line (SCL-2) was more rapidly adapted by use of these conditions (Tilgen W, Boukamp P, Breitkreutz D, et al: In preparation). Growth at lower temperature (30°C) or cocultivation with irradiated 3T3 feeder cells was not advantageous. Rheinwald and Beckett (*43*) reported, however, that successful cultivation of SCC from tongue and facial epidermis depended on the presence of mesenchymal (3T3) cells.

Morphologically, SCC cells in explant and subcultures revealed characteristics similar to those of the tumor biopsy specimen, as far as polymorphism, mitotic activity, abnormalities, and the low degree of keratinization were concerned. The low degree of keratinization was strongly indicated by the rare formation of cornified envelopes. Moreover, the keratin peptide patterns of the epithelial outgrowth in explant cultures of this and other SCC tumors compared well with those of the respective tumor biopsy specimens. In addition, quantitative keratin protein analysis revealed the poor degree of differentiation of the tumor cells, correlating well with the morphologic findings (data not shown). Larger peptide bands (62,000–68,000 daltons), which are major components of epidermis, were detected neither in tumor tissue nor in culture. In regard to the DNA distribution, the cultured cells were also nearly identical to the preparations made from the primary tumor. All these observations strongly indicated that the major tumor cell population of the SCC has been grown in short-term culture.

When early and later passages were compared, the SCL-1 cells demonstrated high phenotypic stability, since the peptides ranging from 45,000 to 59,000 daltons were quite consistent. Tonofilaments, however, seemed to be reduced in later passages, although the cytoskeletal network of keratin fibers remained clearly visible after decoration with specific antibodies.

Abnormal or malignant growth behavior could be tested only after at least 1 year in culture and was clearly positive in the organotypic culture and transplantation assay. At later passages, tumorigenicity of SCL-1 cells was also demonstrated in nude mice, but higher cell numbers and longer latency periods were required as compared to those in the transplantation assay. Although single cell cloning was possible in late passages with the use of conditioned medium, cells did not express anchorage-independent growth (even in conditioned medium). Anchorage-independent growth is not always correlated with tumorigenicity in vivo, particularly with human carcinoma cells (*6, 44–46*), and may often be acquired only at late culture stages. The ability possibly reflects further changes in growth behavior, due to selection in vitro. Up to 20–30 passages, no significant change in transformed growth behavior of SCL-1 cells was noted.

Despite the good phenotypic stability of the SCL-1 cell population in culture, chromosome and DNA analyses clearly demonstrated that genotypic changes occurred after about 1½ years in culture. The shift of tumor cell karyotypes in culture to higher degrees of ploidy as well as increased chromosomal aberrations in relation to the culture time has also been reported for human lymphatic cells lines (*47, 48*). The shift to hyperploidy in SCL-1 cultures, paralleled by an increased growth rate, was evidently not caused by overgrowth of a minor subpopulation since the two marker chromosomes were maintained in 100 and 70% of metaphases from culture passages 2–20. Although biopsy material could not be examined cytogenetically, nevertheless these marker chromosomes were very likely also characteristic for the hypodiploid tumor stemline in vivo. The almost identical DNA distribution in tumor and early cultured cells gives good evidence that the SCC tumor cell population was transferred into culture without major changes.

The predominance of hypodiploid stemlines in SCC of the skin has previously been determined with the use of DNA cytophotometry (*49*). The methodologic advantage of automated cytophotometric DNA analyses over conventional cytogenetic studies is obvious, since large numbers of cells can be rapidly analyzed. Although the technique is not sensitive enough to detect very small changes in chromosome number and structure, variations in DNA content can be determined with a fair degree of confidence. By cytometry alone, however, the slight hypodiploid deviation of the SCL-1 stemline could not be detected, whereas the shift of the karyotype to hyperploid levels was clearly visible.

Marker chromosomes have been studied in human tumors and derived cell cultures to correlate chromosomal alterations with tumorigenicity or specific tumor types (*50–53*). These studies are complicated by the rapid karyotypic changes observed in many tumors and further aberrations occurring during prolonged cultivation. Nevertheless, evidence exists for nonrandom changes of marker chromosomes in human tumor cells. With carcinomas, a frequent occurrence of maker chromosomes involving chromosomes 1, 3, 5, 7, and 8 was observed (*54–56*). In the SCL-1 cell line, described here and in short-term subcultures of a second skin SCC (Tilgen W, et al: In preparation), the most frequent markers involved chromosomes 7 and 1 and possibly chromosome 8. Similar observations were made earlier with an SCC line by Moore et al. (*9*). Further studies with more tumors and derived cell lines are needed to prove whether translocations involving these particular chromosomes are indicative of SCC or have general relevance for transformation. It should also be clarified whether the degree of differentiation and growth behavior of cells in vivo and in vitro are related and are reflected by the respective karyotypes.

The remarkable stability of the genotypic and phenotypic characteristics clearly indicated that the relevant tumor cell population could be maintained for about 10 passages during a period of more than 1½ years. While in further passages the phenotypic expression seemed to be largely conserved, continued genetic changes were observed. Thus our data demonstrate that cell culture models can be used for limited intervals to study the biologic characteristics of carcinoma cells and their sensitivity to therapeutic manipulations, provided the integrity of the cultured cells is carefully determined.

Epidemiological Features of Wilms' Tumor: Results of the National Wilms' Tumor Study[1, 2]

Norman E. Breslow[3, 4] and J. Bruce Beckwith[5, 6]

ABSTRACT—Nearly 2,000 children with Wilms' tumor registered in a national clinical trial during 1969–81 showed high rates of aniridia, hemihypertrophy, cryptorchidism, hypospadias, and other genitourinary anomalies. Patients with bilateral disease, who constituted 5% of the total, had younger ages at diagnosis and an increased incidence of congenital anomalies and renal blastemal rests. Those with multicentric unilateral lesions had more blastemal rests but were otherwise indistinguishable from the unicentric cases. The 20 familial cases had none of the features usually associated with genetic tumors: neither younger ages nor an increase in bilaterality nor associated congenital anomalies. These observations suggest that the fraction of Wilms' tumors that is due to an inherited mutation may be substantially smaller than previously supposed and support the concept that the disease arises from a variety of pathogenetic pathways.—JNCI 1982; 68:429–436.

Several features of the epidemiology of Wilms' tumor suggest that genetic factors may play a major role in its etiology. The occurrence of the disease is remarkably constant among peoples in scattered parts of the world who have different environments, life-styles, and highly variable incidence rates for most cancers (*1*) Regardless of race, country, or epoch of birth, about one child in every 10,000 may be expected to develop by age 15 a malignant tumor of the kidney (*2*), of which the vast majority have the histologic characteristics of nephroblastoma.

Wilms' tumors are well known to be associated with certain congenital defects including aniridia, hemihypertrophy, and various anomalies of the GU tract (*3*). Cytogenetic studies have established that the aniridia–Wilms' tumor syndrome invariably occurs in persons with a specific chromosomal deletion (*4*). Although these cases tend to be sporadic rather than familial (*5*), aniridia has been diagnosed in both members of a pair of identical twins of whom one had Wilms' tumor (*6*). Reports of familial Wilms' tumor are fairly common (*7*). According to a two-stage mutational model for embryonal tumors, the disease may occur in both hereditary and sporadic forms depending upon whether or not the first mutation is germinal or somatic (*8*). Nodular renal blastema, which is found in approximately one-third of patients with Wilms' tumor (*9*), has been suggested as a precursor lesion in individuals who carry the "Wilms' gene" (*10*).

Most of the published information about genetic factors and Wilms' tumor has come from the aggregation of small series or case reports gathered from widely scattered sources. A unique opportunity for systematic study of the subject in a large and relatively unselected population was created by the NWTS. Some relevant data on congenital anomalies among 547 NWTS patients registered between 1969 and 1973 have already appeared (*11*). The purpose of the present report is to extend these observations to the roughly 2,000 patients registered with the study during the past decade, emphasizing particularly the quantitative differences between bilateral-familial versus unilateral-sporadic cases vis-à-vis age at onset, the occurrence of congenital anomalies, and certain histologic findings.

MATERIALS AND METHODS

Study population.—Between October 1969 and March 1981, a completed registration form was submitted to the NWTS Statistical Center for 2,073 patients. Excluded from consideration here were those whose final diagnosis was other than Wilms' tumor: 59 cases of congenital mesoblastic nephroma, 16 neuroblastomas, 7 polycystic kidneys, 6 renal cell carcinomas, and 13 cases with various benign and malignant conditions. Also excluded were 60 patients identified by the NWTS Pathology Center as having monophasic, clear cell, or rhabdoid sarcoma of the kidney (*12*) and 7 patients who were over 15 years of age at the time of diagnosis. This left 1,905 cases for analysis.

There were three different therapeutic trials in force since the beginning of the study (*13, 14*). Most patients were duly randomized on one of these trials and had base-line and follow-up data submitted at regular intervals. Others, including those registered during interim periods following closure of randomization rolls and the start of a new study, followed one of the NWTS protocol therapies without benefit of randomization. A few, whose treatment did not correspond to any of the defined NWTS regimens, were simply registered with the data center according to an agreement with the nearly 100 participating institutions that all Wilms' tumor patients would be reported. Details of their treatment and follow-up were not routinely requested and are substan-

[6] We gratefully acknowledge the contributions made by the many surgeons, pediatricians, and radiation therapists who treated these children and without whom the study would have been impossible. We also extend grateful thanks to Mrs. S. Jacobson, Dr. D. A. Sim, and Dr. P. Raju for technical assistance, and to Dr. N. F. Palmer and Dr. R. W. Miller for their assistance with the design of the study.

TABLE 1.—*Source of study patients*

Case category	No. of cases included in study			
	NWTS1, 10/69–12/74	NWTS2, 1/75–4/79	NWTS3, 5/79–3/81	Totals
Randomized	[illegible]	517	350	1,200
Followed	191	226	59	476
Registration only	121	80	28	229
Total	645	823	437	1,905

tially less complete than those for randomized or followed patients. Table 1 shows the number of cases of each type.

Sources of data.—The two main sources of data on demographic characteristics and congenital defects were the NWTS registration form, available for all study patients, and a family questionnaire which was filled out and returned by the parent or guardian for 1,370 cases. The questionnaire was available for 78% of randomized, 68% of followed, and 47% of registered patients. The registration form specifically requested information from the referring physician on GU anomalies, aniridia or other eye defects, hemihypertrophy, nevi, hemangiomas, neoplasms, and other congenital defects. The questionnaire asked for a history of pregnancies and family illnesses. Neither form was completely reliable; conditions shown on one were sometimes missing from the other (*11*). The occurrence of a few anomalies was ascertained only after careful reading of the pathology-surgery narratives and flow sheets submitted for most randomized and followed cases. Some relevant conditions have undoubtedly gone unreported or unnoticed.

Slides of the tumor specimen from the initial nephrectomy were submitted and reviewed by the NWTS Pathology Center for 74% of randomized, 63% of followed, and 33% of registered patients in this study. Four or more slides were available for 75% of such patients on the first study. Current guidelines for minimal histologic sampling call for one section to be taken for each centimeter of the largest tumor diameter, plus one section for each nodule of a multicentric tumor. Tumors were classified in one of 30 pattern recognition categories, given a percentage breakdown into stromal, blastemal, and epithelial elements, and scored for the presence of focal or diffuse cellular atypism (anaplasia) (*12*). More recently, the presence or absence of renal dysplasia, Beckwith's medullary dysplasia (*15*), blastemal rests, and immature glomeruli has been noted when the histologic sampling was sufficiently complete.

Bilateral and multicentric tumors.—Of the 1,905 cases analyzed, 84 were bilateral at onset, and an additional 19 developed disease in the contralateral kidney during the course of follow-up. Patients in this latter group were too few for separate evaluation and seemed comparable to the 84 vis-à-vis age and other relevant characteristics. Therefore a single category of 103 bilateral cases was utilized in the data analyses. A second category consists of 133 patients with unilateral multicentric lesions. Some of these were identified from the gross description provided by the pathologist making the initial diagnosis. Others were found during the central pathology review with the use of a criterion of separate tumor nodules of distinct histology. Specimens having a contiguous mass of tumor of uniform histology, but with isolated rests of blastema appearing elsewhere in the kidney, were not scored as multicentric. In view of the absence of central review for many cases, and the variability in the histologic sampling for others, the 133 cases cannot be regarded as a complete enumeration of those with multicentric disease. The third category consists of the remaining 1,669 unilateral cases without evidence of multicentricity.

Statistical methods.—Standard statistical methods (*16*) including *t*-tests, chi-square tests and rank sum tests were used to compare the three categories of patients. Since the family questionnaire was available for only 66% of the bilateral versus 72% of the unilateral cases, some of the analyses were adjusted for presence or absence of this source of information with the use of the odds ratio estimator and chi-square test of Mantel and Haenszel (*17*). The shape of the three age distributions was studied by hierarchical fitting of exponential, Weibull, and log gamma models with the use of the maximum likelihood method (*18*).

RESULTS

Age, Sex, and Race

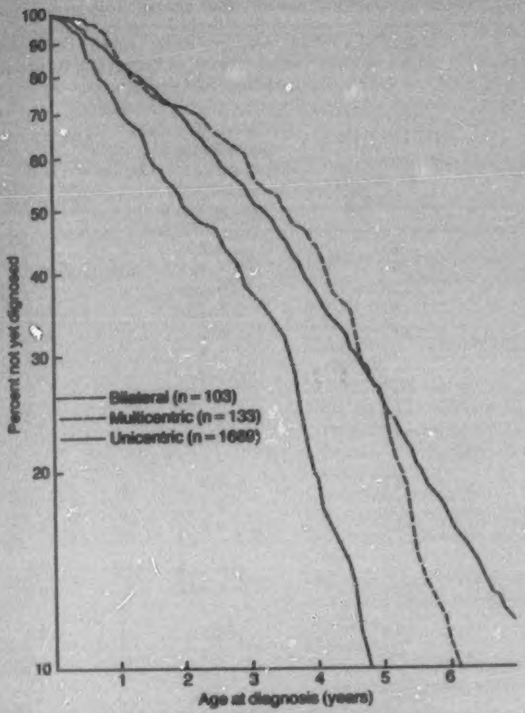
Table 2 summarizes the demographic characteristics of patients in each of the 3 categories. The differences by sex and race are well within the bounds of change ($\chi^2_2=1.9$, $P=0.39$ for sex and $\chi^2_2=4.2$, $P=0.13$ for race), and the averages of the mother's age at birth are nearly identical. Comparison of the age distributions using the rank sum test shows no difference between the multicentrics and unicentrics ($P=0.72$) but shows a highly significant difference between the bilaterals and the combined unilateral group ($P<0.0001$).

Text-figure 1 presents semilog plots of the cumulative age distribution for each category. The shape parameters of the fitted Weibull distributions (table 3) confirm the visual impression of a similar degree of curvature: All three estimates of σ are significantly less than unity ($P<0.0001$), indicating that none of the age distributions are exponential. However, the Weibull model fits quite adequately in comparison with the log normal and other members of the log gamma class.

TABLE 2.—*Demographic characteristics of patients with bilateral, multicentric and unicentric Wilms' tumor*

Demographic characteristic	Wilms' tumor category		
	Bilateral	Multicentric	Unicentric
No. of patients	103	133	1,669
Sex, % male	44.7	42.1	47.8
Age at diagnosis, mo:			
Median	25.5	43.3	36.1
Mean	30.5	44.6	45.1
SD	21.6	29.3	33.9
Race, % nonwhite	13.6	16.0	20.5
Mother's age at birth, yr:			
Mean	25.2	25.0	25.4
SD	5.9	5.4	5.5
(*n*)[a]	(67)	(103)	(1,173)

[a] No. of cases for which mother's age was known.



TEXT-FIGURE 1. —Cumulative distributions of age at diagnosis for three categories of patients with Wilms' tumor.

TABLE 3.—*Parameters of Weibull age distributions fitted to each category of tumor*

Tumor category	Estimated parameters of Weibull distribution[a] ±SE	
	$\alpha = -\log \lambda$	$\sigma = 1/\rho$
Bilateral, *n*=103	3.12±0.09	0.71±0.08
Multicentric, *n*=133	3.56±0.07	0.62±0.05
Unicentric, *n*=1,669	3.49±0.02	0.73±0.02

[a] Parameters were chosen according to Farewell and Prentice (*18*).

An unexpected finding was that the age distribution depended on sex. Male cases tended to be diagnosed a few months earlier, having a mean (±SD) age of 42.1±32.7 versus 46.1±33.7 months for females. The frequency distributions (text-fig. 2) show that male incidence peaks in the 2d or 3d year of life, whereas for females it remains high into the 4th year. The large number of cases ensures that the observed differences are statistically significant (P=0.003 by the rank sum test).

Incidence of Congenital Anomalies

Rates of congenital anomalies among NWTS patients, classified according to the ninth revision of the ICD (*19*), were compared with those from two other large series (table 4). The Collaborative Perinatal Project appears to have the highest incidence yet reported for a general population (*20*). Rates shown in table 4 for this series resulted from aggregation of data for specific conditions coded in the range ICD 741–759 and involved direct adjustment to the race distribution of the NWTS population. A second control series was provided by the surveillance program of the Center for Disease Control in Atlanta, Ga. (Erickson D: Personal communication). Several features complicate the comparability of these data. For example, NWTS patients are examined intensively at diagnosis and have surgical exploration of the kidney and other abdominal organs which would tend to elevate their rates for some conditions. Also, the population series include conditions found at autopsy in stillborn babies and count multiple anomalies within each of the ICD categories, whereas NWTS cases are counted only once. Thus the control rates are shown simply with a view toward providing "order of magnitude" figures for the general population; statistical tests were not considered relevant.

One NWTS patient was reported with spina bifida. Of 8 others with central nervous system anomalies, 5 had hydrocephalus, 2 had microcephaly, and 1 had a meningiomyelocele.

Table 5 lists the characteristics of 16 NWTS patients with aniridia–Wilms' tumor syndrome. Their high frequencies of associated eye anomalies and GU disorders confirm earlier work (*5*). The average age at diagnosis, 24.4±11.2 months, is significantly lower than that for the other cases (P=0.02). There was an assortment of other, mostly minor eye disorders in 7 more children including ptosis, heterochromia, blocked tear ducts, anisocoria, and cataracts. Ear and face deformities in 4 patients included 1 possible case of Noonan's syndrome (i.e., low set ears, slant eyes, and valvar pulmonic stenosis) and 1 with a cleft palate. Cleft palate was the sole anomaly in 1 other patient.

There were 29 patients reported with anomalies of the cardiovascular or respiratory systems of which 3 were associated with the aniridia syndrome (table 5). The remainder of the cases included 9 septal defects, 7 accessory or anomalous renal vessels, 2 coarctations of the aorta, and miscellaneous other conditions. The 13 anomalies of the upper alimentary tract–digestive systems included 3 Meckel's diverticula, 2 high-arched palates, 2 intestinal malrotations,

[d] Rates for males only.

and 1 each tongue tied at birth, macroglossia, imperforate anus, congenital megacolon (Hirschsprung's disease), hyperplasia of the small bowel, and persistent cloacus.

The predominant genital anomalies in males were 25 cases of cryptorchidism and 16 cases of hypospadias; 4 patients had both. Mean ages at diagnosis were 32.9±26.2 and 23.9±20.5 months for the 2 groups. These were less than the mean age of 42.1±32.7 months for all males, and the difference for hypospadias ($P<0.0001$) but not cryptorchidism ($P=0.08$) was statistically significant. Five of the 10 male cases with aniridia had one or the other of the two genital anomalies (table 5). Other kinds of abnormal genitalia were seen in 4 more patients: 2 males and 1 female were pseudohermaphrodites and 1 male had an extra testicular sac.

The most common urinary tract anomalies were double collecting systems in 29 patients or fused kidneys in 7 cases. Other cases were reported with lobulated kidney (4 cases), renal ectopia, hydronephrosis, cystic kidney (2 cases each), malformed kidney, dysplastic kidney, obstruction of the ureter, and female hypospadias (1 each). Because most of these anomalies were discovered in the course of nephrectomy and because results from autopsy series indicate that many such conditions go undiagnosed in the general population (*21*), the control comparisons have little relevance. Similar remarks apply to the 12 cases of accessory spleen coded under ICD 759.

The 51 musculoskeletal anomalies included clubfoot (7 cases), conditions involving the hip (8 cases), face or skull (11 cases), leg or ankle (2 cases), ribs or sternum (6 cases), spine (scoliosis, 5 cases), and the hand (6 cases). There were also single occurrences of spina bifida occulta, phocomelia, Klippel–Feil syndrome, prune belly syndrome, a missing toe, and the combination of claw hand with claw feet. Strawberry nevi, birthmarks, accessory skin tags, or other integumentary disorders coded under ICD 757 were seen in 34 patients.

The average age of 20 male and 27 female patients diagnosed with hemihypertrophy was 39.5 months, almost identical to that for the sample as a whole. One had aniridia and 4 had various anomalies of the GU tract. For 35 of these 47 patients, the laterality of both tumor and hemihypertrophy was known; however, there was no indication that the two were related.

Data were collected on a number of congenital conditions besides those that could be coded to ICD categories 741–759. For example, 21 male cases were reported with inguinal hernia, varicocele or hydrocele, and 2 females had inguinal hernia. Umbilical hernias occurred in 6 males and 8 females, 3 of them in 4 children reported by their institutions as having the Beckwith–Wiedemann syndrome. Hereditary disorders included 3 cases of sickle cell anemia, 2 Hashimoto's diseases, 2 von Willebrand's diseases, and 1 each of hemoglobinopathy and Mediterranean anemia. There were 10 mentally retarded patients without seizures, and 5, all of whom also had other anomalies, with seizures. An additional 5 cases were reported as having seizures but no retardation.

[b] Uc=unicentric; M=multicentic; LB=late bilateral; B=bilateral at onset.

Association of Congenital Anomalies With Bilaterality and Multicentricity

Table 6 compares the incidence of common anomalies among the three patient categories. More than twice as many bilateral than unilateral cases were reported with at least one anomaly ($P<0.0001$). The association was particularly strong with hemihypertrophy and with hypospadias and other abnormalities of the male genitalia. There was no evidence, however, for an excess of congenital anomalies of any kind among the (unilateral) multicentric cases as compared to unicentric cases.

Histopathology

Most tumors, regardless of laterality or centricity, exhibited the typical mixed pattern of stromal, epithelial, and blastemal elements. For one particular subtype, anaplastic blastema, 3 of the 10 cases were found among the bilaterals ($P<0.001$). However, the significance of the finding is obscured by the fact that 30 or more distinct subtypes have been defined (*12*).

More interesting differences between categories were found in the presence of certain embryonic or premalignant structures (table 7). The bilateral and multicentric cases all tended to have a higher frequency of renal dysplasia, Beckwith's medullary dysplasia, blastemal rests, and immature glomeruli. Particularly striking was the occurrence of blastemal rests in more than one-half of the bilateral and multicentric lesions versus 14% of unicentric lesions. However, there was no indication that 175 NWTS patients observed with blastemal rests were diagnosed any earlier than 705 scored negative or uncertain; mean ages (±SD) were 42.3±26.8 and 43.2±32.7 months, respectively.

Familial Wilms' Tumor

There were 20 patients (1.0%) reported who had one or more relatives with Wilms' tumor, a sibling being involved in 7 cases and a parent in 1. These cases generally seem quite comparable to their nonfamilial counterparts (table

TABLE 6.—*Association of selected congenital anomalies with bilaterality and multicentricity*

[a] Significance level based on χ^2_3 statistic for homogeneity.

8). Mean ages for the patient at diagnosis and the mother at birth are 44.4±22.1 months and 26.3±4.8 years, respectively, both figures being close to those for the series as a whole (table 2). Three patients had congenital anomalies, none of them typically associated with Wilms' tumor. Only 1 familial case had bilateral disease and 2 were multicentric; however, several bilateral tumors were reported among the affected family members. The range of cell types and other histopathologic features was fairly characteristic.

DISCUSSION

Certain of the NWTS findings confirm the observations made by Knudson and Strong (*8*) and others (*6, 22*) in support of a two-stage mutational model for the etiology of Wilms' tumor. Other findings conflict with this notion. In agreement are the earlier ages at diagnosis and the higher incidence of associated congenital anomalies for the bilateral cases, although the differences are not nearly so great as in the small study of Bond (*22*), and the younger ages for those with aniridia but not with hemihypertrophy. Similarly, the NWTS data (table 7) confirm an association of blastemal rests with bilaterality which was previously noted in a much smaller series and was used to suggest that nodular blastema is a precursor lesion occurring in patients with the putative mutation (*23*).

An essential feature of the etiologic model is the young median age of the hereditary cases, which are assumed to encompass all bilateral and familial tumors and a fraction of the remainder. Indeed, it is largely on the basis of an age distribution typical of unilateral cases that those accompanied by hemihypertrophy have been identified as sporadic. According to the theory, the hereditary cases occur earlier since only the second mutational event need take place. The original model for both retinoblastoma (*24*) and Wilms' tumor (*8*) asserted further that the ages of such cases followed the "one-hit" or exponential distribution expected from a constant rate of occurrence for this event. However, this was subsequently modified to accommodate a changing population of susceptible embryonic cells (*25–27*). Moreover, the percentage of Wilms' tumors estimated to be of hereditary origin has recently been revised downward from 38 to 15–20% (*28*).

The age distributions of the unilateral and bilateral NWTS cases display rather similar degrees of curvature on the semilog plot and as measured by the shape parameters of the fitted Weibull distributions (table 3): $\rho = \sigma^{-1} = 1.41$ for the bilateral cases and $\rho = 1.37$ for unilateral, unicentric cases. The density of the age distribution for the unilateral–sporadic cases is proportional to the age incidence function which, since these cases predominate numerically, has roughly the shape shown in text-figure 2. The peak in incidence at ages 2–4 is consistent with a rise and subsequent decline in the number of susceptible embryonic cells (*29*). Alternatively, the density of the age distribution for the bilateral–hereditary cases should reflect the attenuation of a population of susceptibles, most of whom acquire the disease. We have not yet attempted to verify the complicated relationship between the two curves which is predicted by the most recent model (*27*).

One aspect of the theory that needs some modification or clarification in light of the NWTS data is the classification of patients with (unilateral) multicentric tumors in the hereditary class. The characteristics of 133 multicentric cases in this series are closer to those of patients with unicentric tumors than to those with bilateral tumors with regard to age at diagnosis and the association with congenital anomalies. The single feature that they share with the bilaterals is a high frequency of association with nodular blastema and other embryonic remnants. While this perhaps fits in with the idea of a common mutational etiology, the observation of identical age distributions for cases with and without blastemal rests does not.

Another group for whom NWTS data fail to confirm earlier observations made in support of the mutational theory is the group of the familial cases shown in table 8, of which tumors 69 and 2,230 have been reported previously (*30, 31*). Although these are admittedly few in number and include 1 or 2 questionable patients, it is instructive that they display none of the features usually associated with genetic tumors: neither younger ages at onset, nor a high degree of bilaterality, nor a heightened association with congenital anomalies, nor a clear pattern of autosomal dominance. However, a greater incidence of bilaterality was apparent among family members with the disease. The concepts of delayed mutation and host resistance have been advanced to explain the occurrence of pedigrees, such as observed here, where affected distant cousins are related via unaffected family members (*32*). Also, the small number of cases means that the story could change dramatically after another decade of case collection and observation. By that time a number of the survivors of bilateral Wilms' tumor (*33*) will themselves be parents, and the answer should be clearer. Nevertheless, the recent report of no tumors being found in 54 children of a series of patients who survived the unilateral disease reinforces our belief that the hereditary fraction may be rather small (*34*).

If bilateral Wilms' tumors are not usually the result of an inherited mutation, one must search elsewhere to explain their earlier age at diagnosis and the clear link to hypo-

spadias and other anomalies. These features could indeed be due to a two-stage process, but one in which the first event occurs postzygotically rather that prezygotically, and early enough in embryogenesis to affect developing renal and genital tissue on both sides of the midline. The age at diagnosis would then be determined by the time it takes for the second event to occur in either of two kidneys. Consequently, the age at diagnosis would be less on the average than if only one kidney were at risk.

The observations made here support the concept that Wilms' tumors may arise by a variety of pathogenetic pathways. One subgroup comprises the aniridia cases, with their young ages, high incidence of associated GU anomalies, and specific chromosome abnormalities. Another group consists of patients with Wilms' tumor and gonadal dysgenesis, for which a common defect in the embryonic urogenital ridge has been suggested as a possible cause (*35*). The cases arising in association with hemihypertrophy seem to form a rather different group; the familial cases, however, may turn out to be a heterogeneous collection, some of which are indeed carriers of a particular mutation and others of which are not.

Another interesting finding from this large and systematic study of patients registered in a national clinical trial is male-to-female sex ratio of 900:1,005=0.896, which is significantly different from unity (P=0.05). This agrees with the ratio of 0.9 found in a French series of 248 cases diagnosed during 1957–67 (*36*) but conflicts with the ratio of 184:151=1.2 observed in 1962–66 in a population-based series (*37*) in Great Britain and with the ratio of 81:66=1.2 observed for kidney tumors under 15 years of age in the Third National Cancer Survey (*38*). Because all these ratios are sufficiently close to 1, further data from incidence registers will be required to resolve the issue of a possible sex difference. Of greater potential significance are the distinct age distributions noted for the two sexes (text-fig. 2). The difference of 4 months in mean ages is rather small; therefore, it could easily have gone undetected in earlier studies with fewer cases. Nevertheless, a similar pattern, which could reflect a slight sex difference in the rate of growth or maturation of susceptible embryonic tissue, was observed in Great Britain (*37*).

Growth and Characterization of Childhood Rhabdomyosarcomas as Xenografts[1,2,3]

J. A. Houghton,[4] P. J. Houghton,[4,5] *and* B. L. Webber[6]

ABSTRACT—Eleven surgical specimens of childhood rhabdomyosarcoma (RMS), two bone marrow samples, and cells from ascitic fluid from 1 patient were implanted sc into immune-deprived inbred CBA/CaJ mice. From these, seven lines of RMS were obtained as xenografts, each retaining the histologic characteristics of the tumor of origin and human lactate dehydrogenase isozymes; these represented 6 of the 11 surgical specimens, whereas one line originated from the transplanted cells from ascitic fluid. It was concluded that childhood RMS has a fairly high frequency of heterotransplantability in this system and that such a laboratory model may prove useful in the development of new therapeutic regimens in this disease.—JNCI 1982; 68:437–443.

RMS represents 5–15% of all malignant solid tumors and 4–8% of all malignant diseases in children under 15 years of age (*1–3*). It is the most common soft tissue sarcoma in children (*4–6*) and represents approximately 10% of the solid neoplasms at this institution (*7*).

In children, RMS is a relatively sensitive tumor to treatment with radiation and several chemotherapeutic agents, particularly cyclophosphamide (*8, 9*) dactinomycin (*10, 11*), and vincristine (*12, 13*), although relatively few agents have been evaluated against previously untreated disease (*14*). The prognosis for patients with advanced disease is poor; thus in one study (*15*) only 56% of patients with incomplete resection or with gross residual but nondisseminated disease and only 29% of those with disseminated disease at diagnosis remained in continuous remission. RMS of the peritoneum and extremities have a poor prognosis (*2, 16*). Because of variations in therapeutic protocols according to the stage or site of primary disease, new therapeutic approaches are difficult to evaluate. Accordingly, an appropriate laboratory model of childhood RMS would afford the opportunity to evaluate, under carefully controlled experimental conditions, new therapeutic regimens in both untreated and drug-resistant forms of RMS. Xenografts of various human cancer types retain many characteristics of the tumor of origin (*17–19*), including chemosensitivity associated with the human disease (*20–23*), and in specific instances show similar responses to those determined in the particular tumor of origin (*24, 25*). The current study demonstrates the growth and characteristics of a series of childhood RMS xenografts, established directly from patient specimens, in mice immune deprived by infant thymectomy and irradiation.

MATERIALS AND METHODS

CBA/CaJ inbred female mice were immune deprived by the technique of infant thymectomy (in 4-wk-old mice), followed 3 weeks later by whole-body irradiation (850 rad; Varian 4 MeV linear accelerator). Within 4 hours of irradiation, each mouse received iv injections of 2.5×10^6 bone marrow cells derived from thymectomized syngeneic mice (*17*). Mice were used for the implantation of neoplastic tissue 2 weeks after the transplantation of murine bone marrow.

Specimens of human RMS were obtained from surgery, needle biopsy, bone marrow aspirate, or peritoneal washout; these specimens were implanted sc into the dorsal flanks of mice, the number of mice used being dependent on the size of the specimen. In general, 2- to 4-mm^3 pieces of tumor were implanted. The incision wound was irrigated with a solution containing penicillin (20,000 U/ml) and streptomycin (20 mg/ml). All procedures were done in a type B laminar flow hood. Mice were caged in an air-conditioned room (26–28°C) lighted for 12 hours each day. Cages, litter, and food (Purina #5010, autoclavable) were sterilized, and mice were placed in fresh cages twice weekly.

We assessed the growth of tumors by measuring two perpendicular diameters at 7-day intervals. As tumor shape approximated that of a sphere, tumor volumes were calculated with the use of the formula $(\pi/6)\times d^3$, where d is the mean diameter (*26*). Tumors were serially passaged when they had grown to 2–3 cm in diameter. Glycogen and collagen contents were estimated histochemically by standard procedures.

Isozymes of LDH were separated by electrophoresis as previously described (*17*). Tumors were rapidly excised and pieces (>100 mg) were stored in liquid nitrogen until analysis. Mouse and human isozymes were separated by flat bed electrophoresis (200 V, 95 min, 2°C) on cellogel analytical strips (Kalex Scientific Co., Manhasset, N.Y.).

Data presented are from tumors between passage #2 and 7 in mice.

RESULTS

Eleven surgical specimens of RMS, two bone marrow samples, and cells from ascitic fluid of 1 patient were

implanted into immune-deprived (T⁻B⁺) mice. Generally, only a few mice received implants due to the small size of the specimen. Six lines of RMS have been established as xenografts from specimens of solid tumor, and one line from ascites cells. No tumors grew from the two bone marrow samples (table 1).

Histology

We have attempted to compare human tumors with their corresponding xenografts with respect to growth pattern (embryonal or alveolar), cell differentiation, cross-striations, and glycogen. Results are summarized in table 2. In no case were major differences noted histologically between the human tumor and the xenograft. The human tumor and xenograft in cases HxRh7 and HxRh10 were essentially identical. Human tumor MS showed more tumor necrosis and slightly better differentiation (lower nucleus-cytoplasmic ratio) than in the xenograft (HxRh8). Focal areas in the human tumor showed an alveolar pattern with loss of cohesion of individual cells. The xenograft showed similar nesting of the cells but no loss of cohesion. The HxRh18 tumors were very similar. A relatively small amount of xenograft material was available for study, and the human tumor did show slightly more collagen than did the xenograft in degenerate areas. A few foci showed an alveolar pattern in the human tumor; this pattern was not seen in the xenograft. Both human tumor RK and xenograft HxRh12 showed good muscle differentiation (fig. 1), cross-striations being demonstrated in both the human and xenograft material. The only minor differences noted were apparently slightly better muscle differentiation in the human tumor, whereas the xenograft showed more spindle-shaped cells than did the human tumor. The sample from 1 patient (tumor RJ) had a more nested pattern than did that of the xenograft, and the xenograft had a looser, more myxoid appearance than did the human tumor; both contained demonstrable cross-striations (fig. 1). HxRh6 was difficult to compare because of the scanty material available in the human biopsy specimen. The xenograft showed necrosis, calcification, and deposition of DNA in vessel walls (as determined by Feulgen stain), none of which was noted in the human biopsy specimen. In essentially all cases, the human biopsy specimens and xenografts were remarkably similar histologically and the differences described were very minor. Each tumor line growing in mice produced human-specific LDH isozymes, indicating the presence of the human genome (fig. 2).

Growth Characteristics

The growth rate of tumors growing as xenografts was determined usually on passage #2, when sufficient numbers of tumors were available. TD_2 ranged from 7 to 20 days for individual lines (table 3), although some variation was noted

TABLE 1.—*Surgical specimens of RMS and growth as xenografts*

Sample	Tumor site	No. of mice	No. of pieces implanted[a]	No. of tumors
HxRh1	Orbit	1	2	0
HxRh3	Lung	2	4	0
HxRh4	Breast	1	1	0
HxRh6	Ascites	13	—	1
HxRh7	Bladder	14	28	5
HxRh8	Groin	1	1	1

TABLE 2.—*Histologic comparison of human tumors and their corresponding xenografts*[a]

Human tumor compared to corresponding xenograft	Tumor pattern	Tumor differentiation	Collagen	Glycogen	Necrosis
Human RRJ	Embryonal with solid nesting	Poor	ND	+++	++
Xenograft HxRh6	Embryonal with solid nesting	Poor	++	+++	++
Human ED	Embryonal	Poor	+++	+++	+
Xenograft HxRh7	Embryonal	Poor	+++	+++	+
Human MS	Alveolar plus embryonal	Fair	+	+++	++
Xenograft HxRh8	Alveolar but without loss of cohesion	Poor	±	+++	–
Human EK	Embryonal	Poor	+	+++	+
Xenograft HxRh10	Embryonal	Poor	+	+++	+
Human RK	Embryonal	Quite good; cross-striations	±	+++	+++
Xenograft HxRh12	Embryonal, more spindled	Quite good; cross-striations	±	+++	+++
Human RJ	Embryonal plus alveolar	Good; cross-striations	++	+++	–
Xenograft HxRh14	Embryonal plus less alveolar	Good; cross-striations	++	+++	–
Human AP	Embryonal plus small amount of alveolar	Moderate	++	+++	++
Xenograft HxRh18	Embryonal	Moderate	+	+++	++

[a] ND = not determined due to poor specimen; +++ = abundant, ++ = moderate, + = slight, ± = occasional, – = absent.

in the rate of growth between xenografts of the same line growing in different host mice. Growth rates of these tumors in mice did not correlate with the degree of tumor cell differentiation; for example, HxRh6, derived from ascites cells, grew most slowly but was poorly differentiated, whereas the moderately differentiated HxRh18 line grew most rapidly. Growth curves for individual tumors are shown in text-figure 1. The growth pattern approximated to logarithmic rather than to Gompertz' growth (i.e., increasing TD_2 with time), as has been observed in xenografts established from human colorectal adenocarcinomas (*26*).

DISCUSSION

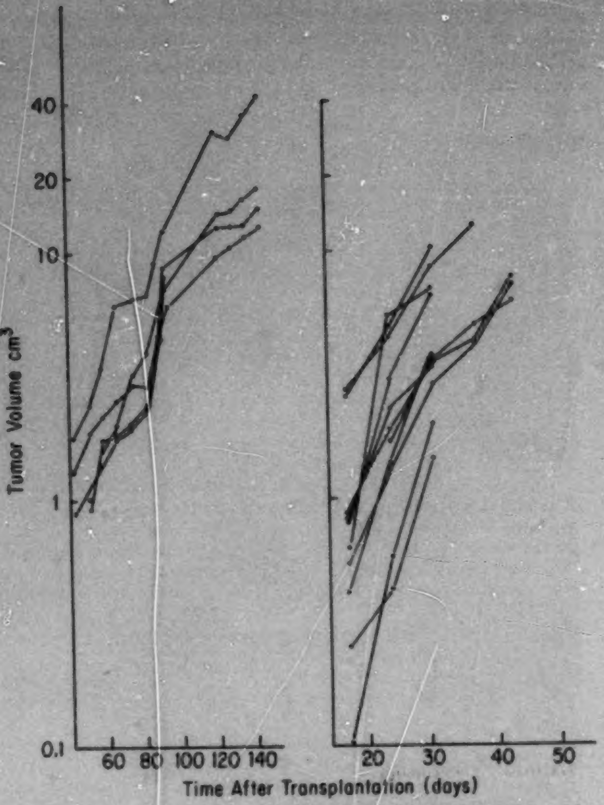
The growth of a human RMS cell line in heterologous hosts, with the use of transplantation into fetal and newborn kittens (intracerebrally) (*27*), into cogenitally athymic mice (*28*), or into mice and hamsters treated with antithymocyte serum (*29*, *30*) has been reported. Our present study demonstrated that RMS tissue obtained at surgery may be transplanted directly into mice T^-B^+ with a high frequency of subsequent tumor development. Considering the limited material available (5–100 mg), rates of takes were high. Six xenograft lines were established, with the use of material derived from 11 human tumors (solid). In 1 case, HxRh8, the line was established from a single implant. Each tumor line established directly from patient samples has proved transplantable into subsequent hosts for periods from 14 to 20 months. During this time no significant changes in growth rate, histology, or transplantability have been observed. Successful grafts were not obtained from bone marrow samples, which is not surprising, since this material may have contained only a few tumor cells, whereas normal cells in the marrow may have induced a T-cell-independent rejection in the host T^-B^+ (*31*). Alternatively, the failure to grow tumor from bone marrow samples may be a result of transplantation into only 4 mice. The 1 sample from ascitic fluid, HxRh6, proved transplantable; however, sc inoculation may not have been the optimal route and injection of such a sample into the leg muscle may prove to be desirable, wherein the ascites cells might be more localized.

Each of the xenografts produced human-specific LDH, indicating retention of the human genome, and each line retained the histologic integrity of its tumor of origin during the period studied. Only HxRh12 and HxRh14 demonstrated cross-striations under the light microscope, as did the original tumors. Subtle differences between xenografts and their human tumors were observed, although the significance of these differences is not known; for instance, the xenograft HxRh8 was less differentiated than its tumor of origin, although it still possessed a similar alveolar pattern. In HxRh6 xenografts established from ascites cells, necrosis, calcification, and deposition of DNA in vessel walls were observed, but these were not present in the specimen of the human primary tumor which, however, was regarded as being of poor quality. Consequently, these observed differences may reflect sampling variation.

TABLE 3.—*TD_2 for xenografts growing at the subcutaneous site*[a]

Tumor line	Passage No.	TD_2, days ± 1 SD
HxRh6	2	19.8±2.3
HxRh7	3	15.9±5.9
HxRh8	3	10.8±3.1
HxRh10	2	12.0±4.3
HxRh12	2	12.5±4.6
HxRh14	2	10.2±2.5
HxRh18	2	7.2±1.5

[a] Tumor fragments were implanted sc, and diameters were measured at 7-day intervals as soon as the tumors became palpable. TD_2 values were calculated during the initial two volume doublings.



TEXT-FIGURE 1.—Growth curves for HxRh6 (*left*) and HxRh18 (*right*) growing subcutaneously in immune-deprived mice.

Whether these xenografts retain the chemosensitivity associated with RMS as a disease or more specifically correlate with the drug responsiveness of the tumor of origin remains to be elucidated. Initial results do indicate that RMS xenografts retain the chemosensitivity associated with the clinical disease. The clinically effective agents, vincristine, cyclophosphamide, dactinomycin and doxorubicin, have each shown significant activity in 1 or more xenograft lines (*32*, *33*). Detailed chemosensitivity of RMS xenografts will be seen in (*33*). The present study has shown that the growth of RMS xenografts is progressive, often with relatively slow TD_2, in the order of 12 days. Each tumor line remains serially transplantable 14–20 months after initial implantation of the human material and retains histologic characteristics of the human tumor. This laboratory model of childhood RMS could prove to be of value, because new classes of agents and many known anticancer drugs, in addition to compounds that have not received evaluation against previously untreated RMS in children, may be examined relatively rapidly in xenografted mice.

Intrastage Prognostic Heterogeneity: Implications for Adjuvant Chemotherapy of Breast Cancer[1,2]

Maurice M. Black, *M.D.*,[3] **Benjamin F. Hankey**, *Sc.D.*,[4] *and* **Thomas H. C. Barclay**, *M.D.*[5]

ABSTRACT—The precise role of the use of adjuvant chemotherapy in the treatment of primary breast cancer has been questioned by some clinicians. One of the most important questions regarding the use of adjuvant chemotherapy is the identification of appropriate patients to receive it. The presence of positive axillary nodes has been the determining factor for the evaluation of chemotherapy in clinical trials. The possibility that other factors should be considered in deciding on the routine use of chemotherapy is discussed here on the basis of data from breast cancer patients diagnosed in the Province of Saskatchewan, Canada, none of whom received chemotherapy as part of their primary treatment. The data illustrate the prognostic heterogeneity that exists among patients with negative axillary nodes and among patients with positive axillary nodes. The implications of such heterogeneity include the possibilities that some patients may not benefit from adjunctive chemotherapy and that some may actually be harmed by it. Specific procedures are described for the analysis of existing clinical trial data to determine whether there is any evidence that some patients may not have benefited from adjunctive chemotherapy. Additional clinical trials would have to be done to substantiate such observations.—JNCI 1982; 68:445–447.

A recent editorial in The Lancet (April 4, 1981) regarding adjuvant chemotherapy for breast cancer patients concluded that "the precise role of adjuvant chemotherapy remains in doubt; adjuvant chemotherapy is still an experimental treatment, and should be confined largely to controlled trials designed to show what sort of patients benefit, for how long, and at what price." The need for more precise prognostic characterization of breast cancer patients selected for adjuvant chemotherapy was also addressed by Packard, et al. (*1*) in 1977 and before that by Black and coworkers (*2–4*). These studies suggested that prognostic heterogeneity was still present among patients grouped according to node involvement. Axillary node involvement is currently the primary determinant of whether or not adjunctive chemotherapy is part of a patient's treatment regimen. This report presents a reanalysis of data previously reported (*4*) in an attempt to further illustrate the prognostic heterogeneity within breast cancer patients grouped by node status. Also, statistical procedures are discussed which, if applied to existing clinical trial data, could lead to further refinement of the identification of breast cancer patients who should receive adjuvant chemotherapy.

MATERIALS AND METHODS

The data analyzed here have been described previously (*4*). The data were obtained from 333 patients with operable invasive breast cancer for whom tumor and lymph node slides were available and who were diagnosed in 1946, 1951, 1960, or 1968 in one of two breast cancer clinics serving the Province of Saskatchewan, Canada. The previous report (*4*) referred to 348 patients; however, those patients who did not undergo radical mastectomy were excluded. None of the patients received chemotherapy as part of their primary treatment. Follow-up on these patients extended into 1972. Various clinical data were obtained for all patients and the slides for each tumor were read by one of us (M. M. B.) for purposes of rediagnosis and determination of various histologic characteristics.

The histologic characteristics of the tumor included NG and the presence or absence of LRE response to the tumor. A LRE response was defined as the presence of either specified amounts of periductal lymphoid infiltrate, or perivenous lymphoid cellular infiltrate associated with the ducts, or specified amounts of lymphoid infiltrate, or perivenous lymphoid infiltrate associated with the invasive tumor. The presence of one or more of these four factors was taken as evidence of an LRE response. Detailed descriptions of these factors have been reported previously (*2–5*).

The statistical methods employed in the analysis of the data included the life table method of computing observed survival rates (*6*) and a multiple regression model referred to as the proportional hazards model (7) for simultaneously assessing the effects of a number of prognostic factors on survival. The use of the proportional hazards model made it possible to attach statistical significance to the effect on survival of each variable included in the model, by testing whether or not the value of its associated regression coefficient was consistent with a value of zero.

RESULTS

Since the patients included in this analysis were diagnosed and treated prior to the use of chemotherapy in the treatment of patients with regional lymph node involvement, they are of particular value in illustrating prognostic heterogeneity with respect to lymph node status in the absence of any effect of chemotherapy. Prognostic heterogeneity by lymph node status is illustrated in table 1. The patients were classified by number of positive nodes, (0, 1–3, ≥4), NG (I, II, or III) of their primary tumor, and whether there was an

LRE response to the tumor. For negative-node patients, the best survival was associated with NG=III, LRE-positive tumors, and the worst survival was associated with NG=I, LRE-negative tumors. For patients with positive nodes a similar relationship to survival was seen for NG and LRE response and the number of nodes positive was also of prognostic significance. Had data on tumor size been available, such data could have provided further evidence of prognostic heterogeneity by node status.

To determine the statistical significance of these observations, the effects on survival of number of nodes positive, NG, and LRE response were simultaneously assessed with the use of the proportional hazards regression model. The estimated coefficients, their standard errors, and the ratio of the estimated coefficients to their standard errors are given in table 2. Variables for age were also included. The variables were introduced into the model as: $X_1=0$ (NG=I), $X_1=1$ (NG=II), $X_1=2$ (NG=III); $X_2=0$ (LRE-negative), $X_2=1$ (LRE-positive); $X_3=0$ (1–3 nodes positive), $X_3=1$ (≥4 nodes positive); $X_4=1$ (age 45–54 yr), $X_4=0$ (otherwise); $X_5=1$ (age≥55 yr), $X_5=0$ (otherwise).

A review of table 2 indicates that none of the variables included for negative-node patients has regression coefficients significantly different from zero at the 0.05 level of significance. For those patients with positive nodes the coefficients for NG and LRE response are significantly different from zero as is the coefficient for number of nodes positive. The absolute value of the estimated coefficients for NG and LRE response are also larger than those for patients with negative nodes indicating that statistical significance is not due to the slightly larger number of patients with positive nodes.

DISCUSSION

These observations provide some evidence that the variation in survival observed for the positive-node patients is not due to chance variation and would suggest the need to question the propriety of treating patients with an already good prognosis with chemotherapy. Even though NG and LRE response were not statistically significant for negative-node patients, the pattern of the survival rates in table 1 is consistent with some effect of NG and LRE response. If the effects of these variables are really smaller in negative-node patients, as is suggested in table 2, then it would have required a larger number of patients to detect such effects as being significant. If the survival rates for negative-node patients in table 1 are taken as representative of the variation in that patient group, it would appear that negative-node patients with NG=I tumors could possibly benefit from chemotherapy, particularly those with no LRE response.

With the use of data on number of nodes positive, tumor size, NG, and LRE response for patients entered into randomized clinical trials, it might be possible to make some further determination of the types of tumors that respond to chemotherapy. An asssessment of deleterious effects of chemotherapy on certain subgroups of patients might also be possible. Detailed procedures for making such determi-

nations from clinical trial data have been described by Byar and Green (*8*). They present statistical methodology including multivariate methods that can be used to identify interactions between the effects of treatment and important prognostic factors. Statistically significant interactions of this type suggest the possibility that the treatment being tested was not the "best" treatment for all patients who received it. They illustrate the use of the methodology by analyzing the data from a clinical trial for patients with stage III or stage IV cancer of the prostate where the treatment being tested was diethylstilbestrol. Their analysis suggested "that young patients with high-grade tumors should have been treated with estrogens, but that older patients with low-grade tumors were harmed by estrogen treatment." They emphasize that such an observation is not definitive, but suggests a hypothesis to be further tested in a clinical trial.

It is important to emphasize that the use of cytotoxic chemotherapeutic agents as adjuvant therapy for breast cancer patients is done under the assumption that acute and chronic morbidity from treatment is justified because of improved recurrence and survival rates. If there is evidence that those patients identified to receive such adjuvant therapy are a prognostically heterogeneous group (as is the case here), then possibly some patients may be unnecessarily treated or even harmed by the treatment even though clinical trials have shown that adjuvant chemotherapy is beneficial for breast cancer patients with positive axillary lymph nodes.

Our primary concern is that the routine use of adjuvant chemotherapy for breast cancer patients with positive nodes may be no more consistent with the biology of the disease than was the routine use of radical mastectomy as the primary treatment for breast cancer. We would hope that an effort will be made to further analyze existing clinical trial data utilizing the previously mentioned procedures (*8*) in an attempt to develop hypotheses that could be tested in future trials. Such studies could further refine the identification of patients who might benefit from adjunctive chemotherapy.

Morphology and Function of Ganglio-*N*-tetraosylceramide-Positive Lymphocyte Mediators of Natural Killer Activity[1,2,3]

Kazuo Shimamura,[4] Sonoko Habu,[4] Hiroyasu Fukui,[4] Akira Akatsuka,[5] Ko Okumura,[6] *and* Norikazu Tamaoki[4,7]

ABSTRACT—More than 90% of nylon wool-passed spleen cells from nude mice reacted with ganglio-*N*-tetraosylceramide (asialo G_{M1}) which eliminated mouse natural killer (NK) cell activity in the presence of complement. The successful enrichment of asialo G_{M1}-positive (asialo G_{M1}^+) cells made possible the demonstration that the number of asialo G_{M1}^+ cells was correlated with NK cell activity as well as with binding frequency to YAC-1 target cells. Morphologically, by light and immunoelectron microscopic examinations, the enriched asialo G_{M1}^+ cells were composed of 90% lymphocytes and 10% large cells with the characteristics of monocytes. However, the asialo G_{M1}^+ lymphocytes (but not the monocytes) bound to the target cells and gave rise to the sequential cytolysis. Although asialo G_{M1}-negative lymphocytes and asialo G_{M1}^+ monocytes were sometimes observed to bind to target cells, cytolytic features of the target cells were not demonstrated. These results strongly suggest that asialo G_{M1}^+ lymphocytes are essential for NK cytolysis by directly binding to target cells.—JNCI 1982; 68:449–455.

We previously reported that cytotoxic treatment with anti-asialo G_{M1} eliminates the NK activity of mouse spleen cells (*1*) and decreases the number of cells reactive with anti-asialo G_{M1} by the indirect immunofluorescence method in vitro as well as in vivo (*2*). Since it was also proved that anti-asialo G_{M1} did not affect T-cell or B-cell function, positive selection of asialo G_{M1}^+ cells allowed us to determine morphologic and functional characteristics of the cell types required for NK cytolysis. Evidence is increasing that NK cells are lymphocytes (*3–5*), whereas the reports are few that monocytes or macrophages are involved in NK cytolysis (*6*). Light and electron microscopic examinations by Roder et al. (*7*) demonstrated that spleen cells that bind to NK-sensitive target cells were lymphocytes.

However, it has not been proved that such lymphocytes express surface antigens such as NK-1 (*8*), Ly-5 (*9*), low Thy-1 (*10, 11*), and Qa-4 and Qa-5 (*12*) for NK cells. In addition, it also remains unclear whether the cells possessing these antigens eventually bind to and directly lyse target cells. Although Tam et al. (*13*) recently reported that NK-1^+ cell populations sorted by a fluorescence-activated cell sorter had increased NK activity as well as increased binding frequency, the detailed features of the binding and lytic process by NK-1^+ cells are still unclear. In this paper, asialo G_{M1}^+ cells from nude mice were enriched by the use of a nylon wool column and then were examined by immunoelectron microscopy to determine whether asialo G_{M1}^+ cells that directly bind to target cells are lymphocytes or some other type of cells. The study reported here, which includes a functional analysis of asialo G_{M1}^+ cells, demonstrated that asialo G_{M1}^+ lymphocytes bind to target cells and thus achieve NK cytolysis.

MATERIALS AND METHODS

Mice.—Nude mice of the BALB/cA background and 8–12 weeks old were obtained from the Central Institute for Experimental Animals, Kawasaki, Japan.

Tumor cells.—YAC-1, a Moloney virus-induced lymphoma in A/Sn mice, was maintained in our laboratory in 10% RPMI-1640.

Enrichment of NK cells.—We prepared the spleen cell suspension by pressing spleens from nude mice between two glass slides in 10% RPMI-1640. Two grams of nylon wool were packed into a 10-ml plastic syringe and moistened with prewarmed (37°C) 10% RPMI-1640. A suspension of 10^9 spleen cells in 10% RPMI-1640 was applied to the column and incubated (37°C, 5% CO_2). After 45 minutes of incubation, the cells were washed from the nylon wool column with 30 ml warm 10% RPMI-1640. The eluate constituted fraction 1. Recovery of the washed-out cells was 2–3% of the applied cells. A subsequent 45-minute incubation of the column was performed, and the second fraction was obtained by washing the column with the same medium (fraction 2).

Fluorescence study on asialo G_{M1}^+ cells.—Indirect staining of the cells with anti-asialo G_{M1} was performed. Rabbit antiserum against asialo G_{M1} was prepared by the method described in the previous paper (*1*). After incubation of 2×10^6 cells with 0.1 ml anti-asialo G_{M1} diluted 1:20 (4°C, 30 min), the cells were washed three times and were stained (4°C, 30 min) with FITC-conjugated goat anti-RIg diluted 1:10. Stained cells were determined under a fluorescence

microscope (Standard IV; Carl Zeiss, Inc., Oberkochen, Federal Republic of Germany).

Immunoelectron microscopic study.—The cells incubated (4°C, 30 min) with pepsin-digested $F(ab')_2$ fragments of anti-asialo G_{M1} were stained (4°C, another 30 min) with $F(ab')_2$ fragments of goat anti-RIg labeled with HRPO by Nakane's method (*14*). After being washed, the cells were fixed for 20 minutes in 2% glutaraldehyde on ice and washed in PBS (pH 7.2) three times. They were incubated (5 min) in Karnovsky's solution (3,3'-diaminobenzidine:4 $HCl-H_2O_2$ solution) at room temperature. After osmium fixation and graded alcohol dehydration, thin sections cut with an LKB-8800 microtome were examined under an electron microscope JEM-100C (JEOL, Tokyo, Japan). We omitted staining some sections with a metal salt to distinguish reaction products from nonspecific density. A control study on the samples treated with normal rabbit serum instead of $F(ab')_2$ fragments of anti-asialo G_{M1} showed no reaction products on the surface of any of the spleen cells.

Determination of asialo G_{M1}^+ large cells.—When stained for anti-asialo G_{M1} by indirect immunofluorescence or enzyme-labeled antibody, the large cells of nylon-passed spleen cells were determined as having diameters of more than 8 μm under a light microscope. Endogenous peroxidase-positive granules were visualized as brown dots and dense granules under light and electron microscopes, respectively, by incubation in Karnovsky's solution after fixation described previously in "Immunoelectron microscopic study."

Target binding assay.—For investigation of the binding of NK cells to target cells, 10^6 spleen cells and 10^5 YAC-1 cells were mixed in 0.2 ml 10% RPMI-1640 and centrifuged at 800 rpm in round-bottomed microtiter plates. After incubation in 5% CO_2 (37°C, 10 min to 4 hr), the cells were pipetted with a micropipette into the microplates and were indirectly stained for anti-asialo G_{M1} by the methods described previously in "Fluorescence study on asialo G_{M1}^+ cells" and "Immunoelectron microscopic study," respectively. When washed by pipetting three times with PBS in the wells, FITC-conjugated cells binding to target cells were counted under a fluorescence microscope. For electron microscopic examination of target-binding cells, the cells stained with peroxidase-labeled $F(ab')_2$ fragments of goat anti-RIg antisera were dropped onto the albumin-coated glass slides and were fixed in 2% glutaraldehyde. The same procedure was performed in the presence of 25 m*M* EDTA, which blocked binding of NK and target cells.

Cytotoxic treatment of spleen cells with anti-asialo G_{M1}.—After 10^7 spleen cells were incubated (37°C, 30 min) with 1:100 diluted anti-asialo G_{M1}/ml, they were washed three times before being incubated (37°C, 30 min) with guinea pig C diluted 1:15. In washed spleen cells, no asialo G_{M1}^+ cells were observed.

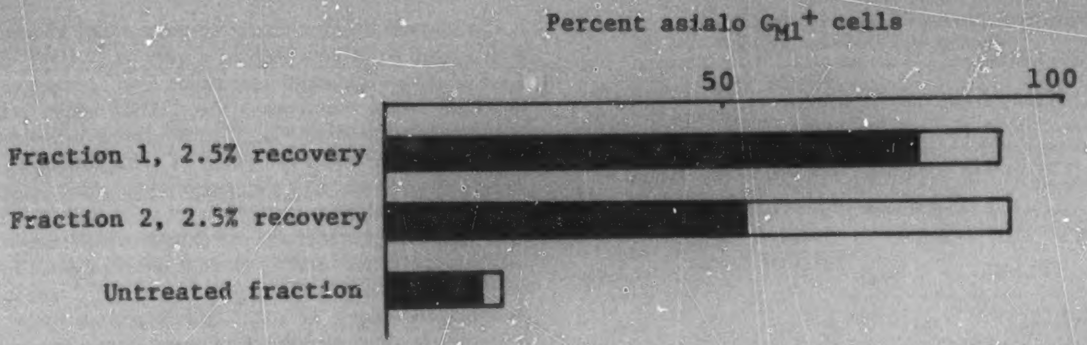
Chromium release assay for NK activity.—The procedure used for mixing 10×10^3 target cells, labeled with ^{51}Cr-sodium chromate, with various numbers of spleen cells was the same as that used for the target binding assay, but all incubations were for 4 hours at 37°C in 0.2 ml Microwell plates. At the completion of incubation, radioactivity released from triplicate cultures was measured by a gamma counter. We determined spontaneous release by culturing ^{51}Cr-labeled target cells alone. We determined maximum release by counting 1 ml of the supernatant after ^{51}Cr-labeled target cells were incubated in 2 ml of water. Percent lysis was computed by the following formula (with standard deviation in triplicates being <2% of the mean value): Percent lysis = [(experimental release − spontaneous release)/(maximum release − spontaneous release)]×100.

RESULTS

Since anti-asialo G_{M1} serum was proved to eliminate mouse NK activity in the presence of C (*1, 15*) and there were two types of asialo G_{M1}^+ cells (small and large) in nude mouse spleens observed under the fluorescent microscope, further morphologic studies were performed with immunoelectron microscopy. The asialo G_{M1}^+ cells were clearly identified by the linear localization of reaction products with anti-asialo G_{M1} antibody on the cell surface at both light and electron microscopic levels. By an indirect staining method, in which a peroxidase-labeled second-step antiserum was used, the asialo G_{M1}^+ small cells were identified to be typical mature lymphocytes possessing heterochromatic nuclei and numerous free ribosomes as well as a few rough ER in the cytoplasm (fig. 1). In contrast, asialo G_{M1}^+ large cells showed characteristics of endogenous peroxidase-positive granules in the abundant cytoplasm, well-developed ER, and less prominent nuclear heterochromatin (fig. 2). From these electron microscopic features, asialo G_{M1}^+ small and large cells were proved to be lymphocytes and monocytes, respectively.

To determine which type of cell was really involved in NK activity, we enriched NK cells from nude mouse spleen cells by using a nylon wool column, which is known to enrich NK activity in spleen cells of euthymic mice (*3, 6*). Spleen cells from non-immunized nude mice were incubated in a tightly packed nylon wool column and then eluted by the two-step method described in "Materials and Methods." Of the spleen cells obtained from fraction 1 (the first wash of the nylon wool column and accounting for 2–3% of the total applied cells), almost 90% were stained for anti-asialo G_{M1} (text-fig. 1). As shown, asialo G_{M1}^+ cells of fraction 1 consisted of 90% small cells and 10% large (>8 μm diameter) cells. By immunoelectron microscopic study, these enriched asialo G_{M1}^+ small and large cells were confirmed to be the same morphologically as the cells referred to as lymphocytes and monocytes in untreated spleen cells. Endogenous peroxidase-positive granules were detectable by incubation in Karnovsky's solution, by which antibody labeled with HRPO was visualized (*see* "Materials and Methods"), and the resulting granules were observed in 70% of the large but in less than 5% of the small asialo G_{M1}^+ cells.

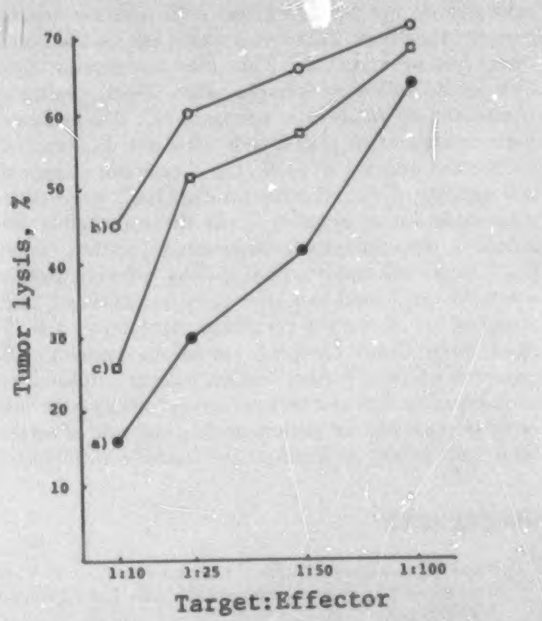
Cells eluted as fraction 2 by the second wash performed after a further forty-five-minute incubation contained the same percentage of asialo G_{M1}^+ cells, but the proportion of large cells was increased to 40%. The results of functional studies of NK cells in which these fractions were used are depicted in text-figure 2. Corresponding to the percentage of asialo G_{M1}^+ cells and especially coincident with the proportion of asialo G_{M1}^+ small cells, NK activity was prominently increased in fraction 1. To know further



TEXT-FIGURE 1.—Morphologic analysis of asialo G_{M1}^+ cells enriched by use of nylon wool column. The untreated fraction was obtained from spleen cells incubated in medium for 45 min at 37°C and was not applied to a nylon wool column. Fraction 1 was obtained from nude mouse spleen cells as the eluate of the first wash and fraction 2 was obtained by the second wash of the nylon wool column (*see* "Materials and Methods"). The recovery percentage was calculated from the fact that 2.5×10^6 cells were obtained by first and second washings of the column after 10^8 spleen cells were applied. Small (▬) and large (▭) cells were determined as having diameters of less than and more than 8 µm, respectively.

whether the asialo G_{M1}^- cells had a role in NK cytolysis, we performed a quantitative add-back experiment in which cells were passed through nylon wool (fraction 1), and asialo G_{M1}^- cells were obtained by cytotoxic treatment with anti-asialo G_{M1}. As shown in table 1, consistent with our previous observation presented in text-figure 2, the number of asialo G_{M1}^+ small cells was correlated with the NK activity, but adding back asialo G_{M1}^- cells did not have any effect on NK activity.

Since the binding of effector and target cells is required for cytolysis by NK cells (*6, 12*), experiments were performed to determine if asialo G_{M1}^+ lymphocytes bind directly to target cells, with the eventual result of target cell lysis, or if other additional phenotypically distinct cells bind to target cells. As shown in table 2, enriched asialo G_{M1}^+ lymphocytes (fraction 1) were shown to bind to target cells more frequently than to lymphocytes from the untreated cell population, which contained a larger percentage of asialo G_{M1}^- cells. In addition, an immunofluorescence study revealed that the percentage of asialo G_{M1}^+ cells in lymphocytes binding to target cells was also higher in fraction 1. Both the binding frequency and percentage of asialo G_{M1}^+ cells in these binding lymphocytes were correlated with NK activity and were confirmed to be abolished by cytotoxic treatment with anti-asialo G_{M1}. Furthermore, a binding inhibition experiment in which cells were treated with EDTA strongly supported the importance of binding for asialo G_{M1}^+ cells to function as NK cells.



TEXT-FIGURE 2.—NK activity of effector cells from a) untreated cells, b) fraction 1, and c) fraction 2 of nude mice. Effector cells are defined in text-fig. 1.

An immunoelectron microscopic examination, in which $F(ab')_2$ was used for staining anti-asialo G_{M1}, was performed to determine if asialo G_{M1}^+ lymphocytes really bind to target cells. In the first 20-minute incubation of target and nylon

TABLE 1.—*Dependence of NK activity on the number of asialo G_{M1}^+ small cells from nude mouse spleens*

25	25	0	55
35	25	10	57
47	25	22	59
85	25	60	58
100	25	75	59

[a] Total is sum of asialo G_{M1}^+ cells (column 2) and G_{M1}^- cells (column 3).

[b] Asialo G_{M1}^+ small cells referred to in text-fig. 1 were determined for fraction 1, which consisted of 88% asialo G_{M1}^+ cells. *See* "Materials and Methods" for description of fraction 1.

[c] Asialo G_{M1}^- cells were obtained by treatment of nude mouse spleen cells with 1:100 diluted anti-asialo G_{M1} and guinea pig C (1:15). After cytotoxic treatment, no asialo G_{M1}^+ cell was observed.

TABLE 2.—*Relationship between binding of asialo G_{M1}^+ lymphocytes to target cells and NK cytolysis*

Treatment	Percent asialo G_{M1}^+ cells in lymphocytes	Percent tumor lysis at effector:target of:		Percent of cells binding to target cells at effector:target of 10:1	
		10:1	100:1	Lymphocytes[a]	Asialo G_{M1}^+ lymphocytes[b]

Untreated	11	10	38	8	28
Anti-asialo G_{M1} plus C[d]	1	0	0	4	2
EDTA[e]	11	0	0	3	ND

[a] The number of cells in all lymphocytes binding to target cells was counted under a light microscope, and the percentage was calculated.

[b] The number of asialo G_{M1}^+ cells in lymphocytes binding to target cells was counted, and the percentage was calculated.

[c] Fraction 1 was obtained as described in "Materials and Methods."

[d] Asialo G_{M1}^- cells were obtained as mentioned in table 1 and in "Materials and Methods."

[e] Spleen cells were incubated with target cells in 10% RPMI-1640 containing 25 m*M* EDTA at 37°C for 30 min.

wool-passed cells, the asialo G_{M1}^+ cells were found to contact target cells with a broad and penetrating projection of their lymphocyte cytoplasm (fig. 3). After 1–2 hours of incubation with asialo G_{M1}^+ lymphocytes (fig. 4), degeneration of fused target cells was observed in the first hour, and the number of degenerated fused cells increased with time. However, target cells bound to asialo G_{M1}^- lymphocytes, which were occasionally found, remained nondegenerated even after 4 hours of incubation (fig. 5). Although large cells, including both asialo G_{M1}^+ and G_{M1}^- cells, were rarely found tightly bound to target cells, they were found gathered around degenerated dying cells and cell debris. All of the above data suggest that asialo G_{M1}^+ but not asialo G_{M1}^- lymphocytes function as NK cells by directly binding to target cells.

DISCUSSION

Successful isolation of asialo G_{M1}^+ cells from spleens of nude mice enabled us to study the detailed morphologic and functional aspects of target cell cytolysis by NK cells. It was concluded that the number of asialo G_{M1}^+ cells correlates positively with NK activity as well as with the frequency of target cell–effector cell contact. Very recently, other investigators (Beaumont TJ, et al: Personal communication) have indicated that more than 60% of effector cells in contact with target cells were asialo G_{M1}^+. These asialo G_{M1}^+ cells seem to be consistent with the target-binding cells of Roder et al. (*7*) or NK-1$^+$ cells with NK activity isolated by a fluorescence-activated cell sorter (*13*). The essentiality of the binding between NK cells and target cells for NK cell activity was also demonstrated in this study in that cytotoxic treatment of the spleen cell population with anti-asialo G_{M1} drastically reduced the cell–cell binding as well as the NK activity.

Immunoelectron microscopic observation revealed that cells bound to targets both at a very early stage and at a later degenerating stage were asialo G_{M1}^+ lymphocytes but not G_{M1}^- ones. Although a few YAC-1 target cells were found to bind to asialo G_{M1}^- lymphocytes, no degenerating or dying target cells were detected. This functional observation considered with the morphologic observation that the nature of the contact of target cells with asialo G_{M1}^+ and G_{M1}^- lymphocytes did not differ strongly suggests that target and effector binding alone is not always sufficient for target cell lysis in the NK system, although it was sufficient in the CTL system (*16, 17*). While a number of studies regarding binding and the subsequent lytic process of target cells in CTL and NK systems have been reported, the lytic mechanism has not been satisfactorily defined, particularly at the molecular level (*16–19*). Recently, it has been reported that T-cell-mediated and NK-cell-mediated cytolysis were blocked by the addition of anti-Lyt-2 (*20, 21*) and anti-Ly-5 (*9*), respectively. It is likely that the surface antigens function in the two types of cytolysis. We used anti-asialo G_{M1} alone in a blocking experiment, but target cell lysis was not affected (unpublished data). The same result was also reported for anti-NK-1 antiserum (*13*). Asialo G_{M1} expressed on NK cells, therefore, seems unrelated to "recognition" receptors and/or structures for NK lysis.

Anti-asialo G_{M1} was shown to react not only to a subpopulation of lymphocytes but also to less than 10% of nylon wool-passed cells, which we refer to as monocytes because of their morphologic characteristics. The involvement of these asialo G_{M1}^+ monocytes in NK activity could not be ruled out because both asialo G_{M1}^+ lymphocytes and monocytes are simultaneously eliminated by cytotoxic treatment, resulting in abolished NK activity. However, the morphologic observation that asialo G_{M1}^+ monocytes rarely bind to target cells and do not bind to target cells that are degenerating suggests that these monocytes might not be associated with direct lysis of target cells. They may function as "accessory" cells as do Ia$^+$ macrophages when T-cell proliferation is stimulated by antigens or mitogens (*22, 23*); however, cytotoxic treatment of spleen cells with anti-Ia serum did not reduce the number of asialo G_{M1}^+ cells nor reduce the NK cell activity (*24*). Whether asialo G_{M1}^+ large cells are a subpopulation of accessory cells distinguishable from Ia$^+$ accessory cells presents an interesting question. Since asialo G_{M1}^+ large cells are morphologically different from typical macrophages found as a peritoneal exudate cell and characterized by abundant cytoplasm containing a well-developed large Golgi complex, numerous vesicles, ER, and eccentric nucleus, further studies such as combination of or recovery of surface markers and single cell agarose assay will be of importance for understanding the role of asialo G_{M1}^+ large cells as well as macrophage function in NK activity.

Friend Erythroleukemia Virus Complex: Role of Viral Components in Modifying Erythroid Differentiation in Mice[1,2,3]

Barbara Fagg[4,5,6] *and* Wolfram Ostertag[4,7]

ABSTRACT—The present study was carried out to determine which component of the polycythemic strain of Friend erythroleukemia virus (FV-P)—Friend helper virus [Friend murine leukemia virus (F-MuLV)] or the replication-defective spleen focus-forming virus (SFFV)—is responsible for inducing erythropoietin-independent erythropoiesis and expansion of the erythroid compartment in infected mice. F-MuLV and SFFV were cloned in SC1 cells to give a cell line 643/22N, which released only F-MuLV and SC204, a nonproducer cell line carrying SFFV. On superinfection with specific helper viruses, SC204 yielded further cell lines, which released SFFV in conjunction with 1) Friend, 2) Moloney, or 3) Gross helper viruses. With the use of an in vitro colony formation assay to monitor erythropoiesis in the bone marrow of inbred DBA/2J mice infected with any of the virus preparations containing SFFV plus helper virus, the erythroid precursor cell population was found to become erythropoietin-independent and amplified; adult mice infected with any of the helper viruses alone did not develop any symptoms of Friend disease. Thus the biologic activity of the FV-P complex was unaffected by replacement of the F-MuLV with an unrelated helper virus (Moloney or Gross). These results indicated that the SFFV component of FV-P is responsible for modifying erythroid differentiation in adult mice.—JNCI 1982; 68:457–460.

Friend virus causes an erythroleukemia in adult susceptible mice. Two strains of the virus have been distinguished in infected mice: FV-A and FV-P. Mirand (*1*) obtained FV-P from animals infected with the original virus FV-A, which had been isolated by Friend (*2*). Committed erythroid precursor cells appear to be the major target cells for both strains of Friend virus (*3, 4*), and in vivo studies have shown that, after infection by FV-P, erythropoiesis rapidly becomes independent of the normal regulator, Epo (*5*).

With the development of in vitro colony formation assays for erythroid precursors (*6, 7*), it was possible to examine the differentiation of erythroid precursors from virus-infected animals in vitro. In cultures of normal mouse bone marrow, the formation of early (2-day) erythroid colonies derived from the CFU-E (a committed erythroid precursor cell near the end of the erythroid pathway) is strictly dependent on the presence of Epo in the culture medium. Growth of Epo-independent colonies from the bone marrow of FV-P-infected mice was first described by Liao and Axelrad (*8*) and Horoszewicz et al. (*9*) and was shown to be a direct consequence of virus infection.

FV-P is not a single entity but comprises an SFFV that is defective and a helper virus F-MuLV that is required for replication. It was therefore of considerable interest to determine which of these FV-P components causes erythropoiesis to become Epo-independent and produces overt disease in the mouse—properties of SFFV, evidenced in (*5, 10, 11*), although such evidence is necessarily of an indirect nature since SFFV is replication-defective and cannot be studied independently of a helper virus. Our approach was to exchange the Friend helper virus with other unrelated helper viruses, which do not themselves alter erythroid differentiation, and to examine erythroid colony formation in cultures of bone marrow taken from mice infected with these new virus complexes. A similar rationale has been used to examine the role of the helper virus in the transformation of lymphoid cells by the Abelson virus complex (*12, 13*) and of hematopoietic cells by Kirsten virus (*13*).

MATERIALS AND METHODS

Cell lines and virus isolates.—Cell lines were grown in a modification of Eagle's minimum essential medium containing 10% FCS, as described previously (*14*). F4–6 is a subclone of the cell line F4N, which consistently releases high levels of FV-P (*15*). The SFFV and F-MuLV components of FV-P were cloned by successive end-point dilutions (*16, 17*) to give SC204, which is an SFFV-positive, F-MuLV-negative cell line, and 643/22N, which is SFFV-negative and F-MuLV-positive. The SFFV was rescued from SC204 cells by superinfection with the following cloned viruses: F-MuLV from 643/22N cells, which is free of detectable xenotropic sequences (Ostertag W: Unpublished work); M-MuLV from cell line 1.1A (provided by Dr. R. Weinberg, MIT, Cambridge, Mass.); and Gross helper virus (Gross-MuLV) from NIH Swiss mouse fibroblasts (provided by Dr. D. Baltimore, MIT) to give cell lines that released SFFV plus F-MuLV, SFFV plus M-MuLV, and SFFV plus Gross MuLV, respectively.

Virus infection.—Supernatants from the cell lines were routinely assayed for reverse transcriptase activity (*15*) and for SFFV titer determined by the spleen focus-formation assay

(*18*) and expressed as SFFU per milliliter of supernatant. When the reverse transcriptase activity was approximately 10 pmol thymidine 5′-triphosphate incorporated into trichloroacetic acid-precipitable material per 10 μl supernatant, the supernatants were concentrated 10–100 times with the use of an Amicon DC2 hollow-fiber unit fitted with a 100,000-molecular weight cut-off membrane followed by use of an Amicon 402 unit fitted with an XM300 membrane. These preparations were filtered (0.2 μm, Acrodisc, Gelman Instrument Co., Ann Arbor, Mich.) and stored in liquid nitrogen until use. Preparations were thawed, diluted as appropriate, and administered iv to 3- to 4-month-old male DBA/2J mice.

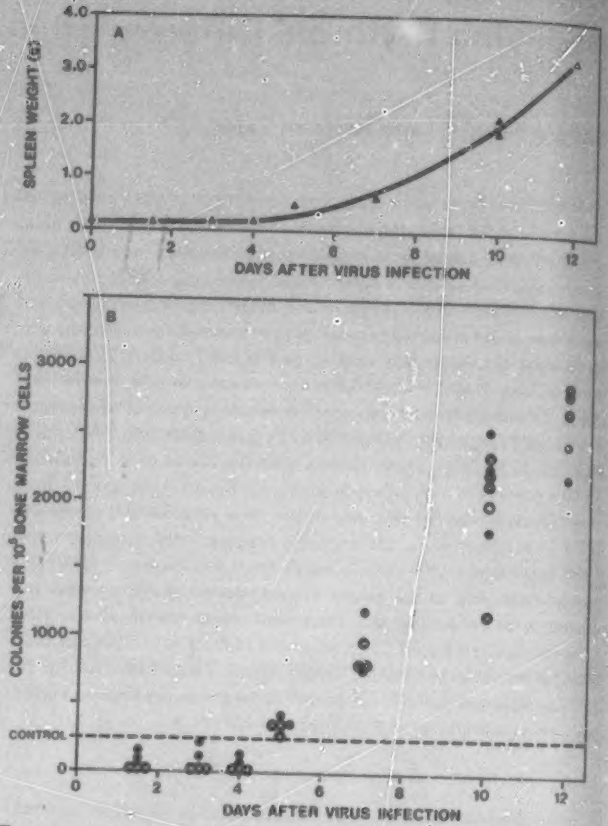
Methyl cellulose cultures.—Virus-infected mice were used for experiments at a time when the spleen was easily palpated. Uninfected animals of a similar age were used as controls. Mice were killed by cervical dislocation, the spleen and both femurs were removed under sterile conditions, and the wet weight of the spleen was recorded. The marrow was flushed from both femurs into α-medium (Flow Laboratories Inc., Bonn, Federal Republic of Germany) containing 2% FCS and was dispersed by repeated passage through syringe with a 22-gauge needle. The resultant single cell suspension was plated in α-medium containing 25% FCS, 0.1 m*M* α-thioglycerol, and 1% methyl cellulose (Fluka, Buchs, Switzerland), essentially as described by Iscove et al. (*7*). For each bone marrow sample, duplicate cultures were prepared containing 0.5, 1.0, and, in some experiments, 0.25 and 2.0×10^5 cells/ml with or without 0.15 U of human Epo/ml (this dose of Epo was shown to give maximum numbers of CFU-E colonies in normal bone marrow cells). Human Epo was either provided by Dr N. Iscove (Basel Institute for Immunology, Switzerland) or was prepared by means of the same procedure in (*7*) and calibrated in vitro against Step III Epo (Connaught Medical Research Laboratories, Ontario, Canada). After 2 days' incubation at 37°C in 5% CO_2-air, the number of colonies arising from CFU-E cells (CFU-E colonies) was counted with an inverted microscope (× 100). We confirmed the identification of colonies as erythroid by staining with benzidine either in the culture dish or after smearing colonies on a glass slide. In all cases examined a linear relationship existed between the number of cells plated and the number of colonies formed both in the presence and absence of Epo.

RESULTS

Effects of FVP on the CFU-E Population

The number of CFU-E colonies formed in the presence and absence of Epo was determined from 1.5 to 12 days after infection of DBA/2J mice with FVP derived from F4–6 cells. Over the period of 5–12 days after infection, a steady increase in both spleen weight (text-fig. 1A) and the numbers of Epo-dependent and Epo-independent colonies (text-fig. 1B) was observed. These results are in close agreement with those of other authors (*8, 19*), who used FV-P that had been continually passaged in mice, except that the virus from F4–6 cells resulted in a larger expansion of the CFU-E compartment.

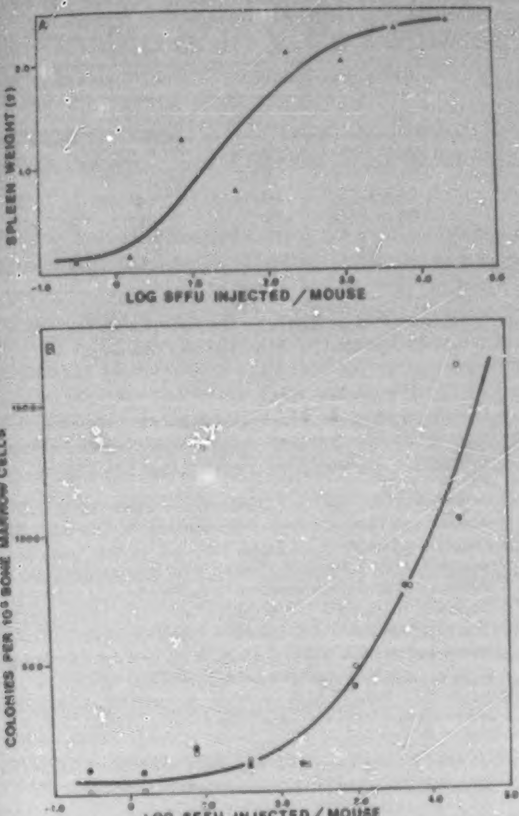
The relationship between the number of SFFU administered and the induction of splenomegaly, Epo independence, and amplification of the CFU-E population was examined in more detail with the F4-6-derived virus. For spleen weight, a plot of logarithm dose versus response was sigmoid (text-fig. 2A) and, at all doses suprathreshold for this response, the CFU-E population was Epo-independent (text-fig. 2B). Expansion of the CFU-E population was also related to the amount of SFFV injected (text-fig. 2B), although the threshold for this response was higher than that for induction of Epo independence or splenomegaly. For this reason, mice were used in subsequent experiments only when they exhibited pronounced splenomegaly (≈2 g wet wt).



TEXT-FIGURE 1.—Effects of FV-P infection (2×10^3 SFFU/mouse, derived from F4–6 cells) on: A) spleen wt (▲) and B) numbers of CFU-E colonies developing in bone marrow cells grown for 2 days in the presence (●) or absence (○) of 0.15 U Epo/ml. The control value (- - - -) represents the number of CFU-E colonies found in normal bone marrow cells cultured in the presence of Epo

Cause of Epo-independent Erythropoiesis: SFFV or F-MuLV?

The SFFV-positive, F-MuLV-negative nonproducer cell clone SC204 was superinfected with F-MuLV, M-MuLV, or Gross MuLV. Reverse transcriptase assays indicated that the 3 resultant cell lines released similar levels of virus (table 1), although the Gross MuLV infected cell line required longer to attain this level. However, the SFFV titer differed



TEXT-FIGURE 2.—Relationship between the number of SFFU (from F4–6 virus) injected/mouse and A) spleen wt (▲) and B) numbers of CFU-E colonies developing in bone marrow cells grown for 2 days in the presence (●) or absence (○) of 0.15 U Epo/ml, when the animals were killed 20 days after virus infection.

markedly between the 3 cell lines (table 1). The ratio of SFFV to reverse transcriptase activities was at least fiftyfold higher in SC204 cells infected with F-MuLV than in those exposed to M-MuLV or Gross MuLV. Experiments involving M-MuLV or Gross MuLV were therefore conducted with both the cell supernatants and the virus concentrates. All virus complexes examined induced splenomegaly in all mice when doses greater than 50 SFFU/animal were injected.

Erythroid colonies developed in the absence of Epo when bone marrow cells from animals infected with any of the SFFV plus helper virus preparations were grown in vitro (table 2). This is in contrast to normal bone marrow cells requiring Epo to complete their differentiation in vitro (table 2). In all cases, similar numbers of erythroid colonies were formed in the presence or absence of Epo, indicating that almost the entire CFU-E population had become Epo-independent as a result of virus infection. Induction of Epo independence was not dependent on the helper virus present with SFFV. Adult mice were unaffected by inoculation with comparable doses of F-MuLV, M-MuLV, or Gross MuLV alone; they showed no evidence of splenomegaly or symptoms of Friend disease.

In addition to becoming Epo-independent, the CFU-E population was amplified in animals infected with F4–6-derived FV-P, SFFV plus F-MuLV, and concentrated preparations of SFFV plus M-MuLV or SFFV plus Gross MuLV (table 2). The absence of erythroid expansion in mice inoculated with untreated cell supernatants containing SFFV plus M-MuLV or SFFV plus Gross MuLV can be attributed to the low amount of SFFU in these virus preparations since text-figure 2 demonstrates that FVP administered at an equivalent SFFU dose also caused the CFU-E population to become Epo-independent without altering its size.

DISCUSSION

Epo-independent erythropoiesis is a prominent feature of FV-P infection in vivo (*5*). The results presented here provide a direct demonstration that this change is caused by the SFFV component of the virus and not the F-MuLV component. Previously, some uncertainty existed concerning the role of SFFV and F-MuLV in the induction of Friend disease. Some evidence indicating the importance of SFFV has been obtained in studies showing *a*) that no Epo-independent erythropoiesis is found in the absence of SFFV in vivo (*5*) or in vitro (*11*) and *b*) that bone marrow cells infected with FV-P in vitro develop erythroid colonies independently of Epo in proportion to the number of SFFU used for infection (*10, 11*). However, recent data indicate that the helper viruses isolated from both FV-A and FV-P are capable of inducing an erythroleukemia (splenomegaly and erythroid expansion but not Epo independence) in newborn but not adult mice (*20, 21*). Furthermore, studies of the Abelson virus complex, which also comprises a helper virus and a replication-defective component, suggest that the helper virus is required for lymphocyte transformation (*12, 13*).

This question has been difficult to answer directly because SFFV is replication-defective and therefore cannot function without a helper virus. In the present study, this problem was circumvented by construction of virus pseudotypes that contained helper viruses unrelated to F-MuLV. Regardless of the helper virus present with SFFV, all complexes prepared were capable of inducing both Epo independence and

[a] 0.15 U EPO/ml. Virus preparations and assays are described in "Materials and Methods." Two preparations of SFFV plus M-MuLV and SFFV plus Gross MuLV were used: I=untreated cell supernatant, II=supernatant concentrated as described in "Materials and Methods."

[b] Values are means of data from 3 to 6 separate mice.

some degree of erythroid expansion, demonstrating that it is the SFFV that is primarily responsible for modifying erythropoiesis in FV-P-infected mice. These data are reinforced by recent studies (*21, 22*) (in which the helper viruses from FV-A and FV-P complexes were reciprocally exchanged) indicating that SFFV determines the nature (anemia or polycythemia) of the disease in vivo.

It is interesting that erythroid expansion was only observed when concentrated preparations of SFFV plus M-MuLV or SFFV plus Gross MuLV were used. The possibility that the helper viruses may carry a common function that affects the size of the erythroid population cannot be entirely excluded. However, the untreated virus preparations contained very low levels of SFFV: An equivalent dose (SFFU) of FV-P (F4-6) similarly produced Epo independence but no erythroid expansion, whereas higher doses induced both changes (text-fig. 2). Therefore, SFFV appears to control the size of the erythroid population in addition to its responsiveness to Epo, although the threshold for expression of these functions may differ.

The present study provides strong evidence that it is the SFFV component of Friend virus that induces the symptoms of Friend disease in mice and indicates that F-MuLV principally serves a replicative function.

Growth and Spontaneous Regression of Swine Melanoma: Relationship of In Vitro Leukocyte Reactivity[1,2,3]

Jane Berkelhammer,[4,5,6,7] Bonnie M. Ensign,[4,5,8] Reuel R. Hook, Jr.,[4,9] Cynthia J. Hecker,[4,5] Gerald D. Smith,[4,10] *and* Ronald W. Oxenhandler[6,11,12,13]

ABSTRACT—A visual microcytotoxicity technique was used to evaluate the leukocyte reactivity of melanoma swine against allogeneic swine melanoma target cells. Peripheral blood leukocytes, which had been collected and cryopreserved in liquid nitrogen at various times during in vivo tumor growth and regression, were thawed and tested on the same day. Comparison of longitudinal leukocyte reactivity with in vivo tumor volume indicated that swine with regressing melanomas exhibited increased leukocyte reactivity during tumor regression. Swine with maximum tumor volumes less than 30,000 mm³ exhibited patterns of leukocyte reactivity that paralleled the patterns of in vivo tumor growth and regression. However, swine with maximum tumor volumes greater than 30,000 mm³ demonstrated increased in vitro leukocyte reactivity at the time of maximum in vivo tumor volume. Histopathologic analyses revealed that increases in tumor volume were frequently a result of host inflammatory cells, particularly pigment-laden macrophages, infiltrating the tumors. Thus at the time of maximum tumor volume, malignant melanocytes were proportionately decreasing in number while pigment-laden macrophages were proportionately increasing. These studies provide additional evidence that the spontaneous tumor cell regression of swine melanoma is associated with immunologic events and that assays of leukocyte reactivity are useful in vitro correlates of host antitumor immunity.—JNCI 1982; 68: 461–468.

Results of in vitro leukocyte cytotoxicity assays in cancer patients have been difficult to interpret because of the frequent toxicity observed with leukocytes from tumor-free individuals and because of the wide technical variation in assays performed on different days (*1*). The demonstration by several investigators (*2–5*) that cryopreserved leukocytes retain their reactivity in in vitro immunologic assays has permitted the simultaneous testing of several samples collected at various times, thus minimizing the day-to-day variation in assays.

Using cryopreserved leukocytes from melanoma patients and tumor-free donors, Berkelhammer et al. found that melanoma patients receiving either autologous (*2*) or allogeneic (*6*) irradiated melanoma cells plus BCG exhibited increased leukocyte reactivity against allogeneic melanoma cells. However, the increase in reactivity did not correlate with the clinical response to the immunotherapy. It was not clear whether the lack of correlation between in vitro leukocyte reactivity and the clinical course of human melanoma represented a lack in the assay system or was instead a result of the fact that most of the melanoma patients had tumor burdens too great to be destroyed by immunocompetent leukocytes in vivo.

The Sinclair swine melanoma system provides a unique opportunity to resolve some of the controversy surrounding in vitro leukocyte reactivity assays. Swine melanoma, while very similar histopathologically to human malignant melanoma, exhibits an extremely high rate (90%) of spontaneous regression. Evidence exists both in vivo and in vitro (*7–11*) that a host immune response plays a role in the spontaneous regression of this neoplasm. The objective of this investigation was to determine if in vitro leukocyte reactivity to swine melanoma cells could be correlated with in vivo tumor volume.

MATERIALS AND METHODS

Swine.—The Sinclair melanoma swine used in this study were derived from miniature swine originally developed at the Hormel Institute, Austin, Minn. These swine were derived from matings of melanoma females × melanoma males. All animals were housed indoors and given free access to water and a commercial swine diet that contained 18% protein. The swine were examined individually for the presence of melanocytic lesions within 72 hours after birth and at 2-week intervals thereafter. Total tumor volume was determined as the sum of all raised cutaneous lesions; individual tumor volumes were calculated as cylinders. Serial

laparotomies and thoracotomies on 13 swine indicated that internal tumors did not represent a significant portion of the total tumor volume.

To limit the variables affecting in vitro leukocyte reactivity, we did not perform sequential biopsies on most animals studied prospectively in this report. On 2 pigs (#5319 and 5434) sequential biopsies were done with aseptic technique. Tissues for light microscopy were processed as previously described (*7*).

Previous gross classification schemes in which the swine were classified as progressors or regressors according to changes in measured tumor volume were not used in this study. This practice has resulted in the frequently fallacious assumption that neoplastic cells were responsible for the change in the size of the *tumor*. Tumor is used here in the classical gross sense to mean swelling.

Media.—EMEM—C used for all cell culture procedures consisted of Eagle's minimum essential medium (Auto-Pow MEM; Flow Laboratories, Inc., McLean, Va.) supplemented with sodium bicarbonate, 4 m*M* L-glutamine, 1% vitamins, 1% sodium pyruvate, 1% nonessential amino acids, 100 IU penicillin and 100 μg streptomycin/ml, 25 μg Fungizone/ml, 30 m*M* HEPES[14] buffer (Flow Laboratories, Inc.), 50 μg gentamicin/ml (M.A. Bioproducts, Walkersville, Md.), and 8% FCS (KC Biologicals, Lenexa, Kans.). EMEM—F contained the same ingredients as EMEM—C, except that 12% dimethyl sulfoxide was added and 30%, rather than 8%, FCS was added.

Target cells and leukocytes.—An allogeneic swine melanoma cell line, #4187, which was established in culture as described previously (*10*), served as the target cell population for all leukocyte microcytotoxicity assays. PBL were separated from whole blood on a Ficoll-Hypaque gradient (Histopaque-1077; Sigma Chemical Co., St. Louis, Mo.). Heparinized blood was diluted with an equal volume of PBS, and four volumes of diluted blood were layered onto one volume of Ficoll-Hypaque. The gradient was centrifuged at 750×*g* at room temperature for 30 minutes, and the middle leukocyte-rich layer was removed and washed with PBS. The washed PBL were then suspended in EMEM—F and frozen in liquid nitrogen as described below. It should be noted that 750×*g* is considerably greater than the speed usually described for separation of human leukocytes. However, this was found to be the optimum rate for the separation of swine leukocytes.

For cryopreservation of leukocytes and tumor cells, cells were suspended in EMEM—F and placed in plastic serum test tubes (A/S Nunc, Roskilde, Denmark). The vials were then placed in a −70°C freezer for at least 24 hours and then stored in liquid nitrogen until used. Before use, frozen samples were thawed rapidly in warm water, diluted with EMEM—C, and washed by centrifugation. Cell viability was assessed by trypan blue exclusion.

Leukocyte microcytotoxicity.—A modification (*2*) of the microcytotoxicity technique of Takasugi and Klein (*12*) was used. Melanoma cell monolayers were harvested by trypsinization, and the number of cells was adjusted to a concentration known to yield 100–400 cells/well after plating. The tumor cell suspension was dispensed in MicroTest plates (#3034; Falcon Plastics, Oxnard, Calif.) in volumes of 0.01 ml/well. The plates were then wrapped in moist gauze and placed in a plastic box with the lid slightly open, and the box was incubated at 37°C in a CO_2 incubator for 12–24 hours. Leukocytes were then thawed, washed in EMEM—C, counted, and added to the tumor cells at concentrations of 1×10^5/0.01 ml. Control groups consisted of tumor cells without leukocytes. Each leukocyte and control group consisting of eight replicates was distributed over the entire plate rather than in horizontal rows to randomize variability in cell plating caused by position on the plate. The leukocyte-tumor cell mixture was then incubated for an additional 40–48 hours.

The leukocytes were then removed, and the surviving tumor cells were visually counted (*2*). Visual counts were assessed after the remaining cells were fixed with acetone-alcohol and stained with Giemsa. Survival fractions were determined by dividing the mean number of tumor cells remaining in wells containing leukocytes by the number remaining in wells without leukocytes (medium control).

RESULTS

Comparison of Fresh Versus Frozen Swine PBL

Swine PBL from 2 donors were tested immediately after preparation and after storage in liquid nitrogen for 1 week. The results shown in table 1 indicate that there was no decrease in leukocyte reactivity (i.e., increase in tumor cell survival) after cryopreservation of the leukocytes.

Relationship Between Leukocyte Reactivity and In Vivo Tumor Volume

For the investigation of the relationship between leukocyte reactivity and in vivo melanoma growth and regression, the leukocyte reactivity of a swine (#5319) with many small tumors which ultimately regressed was compared to that of a swine (#5338) with a large rapidly growing tumor. Text-figure 1A shows that both the rate of tumor growth and the maximum tumor volume (150,000 mm^3) were much greater in swine #5338 than in #5319. Cryopreserved leukocytes from both animals were then tested simultaneously against

TABLE 1.—*In vitro reactivity of swine leukocytes*[a]

Lymphocyte source	Mean No. of tumor cells ± SD (% survival)[b]	
	Before freezing	After freezing
Swine #5767	184±52 (79)[c]	125±34 (83)[c]
Swine #5771	160±38 (68)[d]	102±26 (68)[d]
Medium control	234±63	150±35

[a] Lymphocytes were tested in a 48-hr visual microcytotoxicity assay before freezing or after freezing with subsequent storage in liquid nitrogen for 1 wk.

[b] Mean is of 8 wells/group. Percent survival was calculated as (mean cell number in experimental wells/mean cell number in medium control wells) × 100. Differences between experimental and control groups were tested by two-tailed Mann-Whitney *U* test.

TEXT-FIGURE 1.—A) Comparison of tumor growth in progressor swine #5338 (- -■- -) and regressor swine #5319 (—●—). B) Comparison of leukocyte reactivity in progressor swine #5338 (▥) and regressor swine #5319 (▨). Cryopreserved leukocytes were tested simultaneously in a visual microcytotoxicity assay.

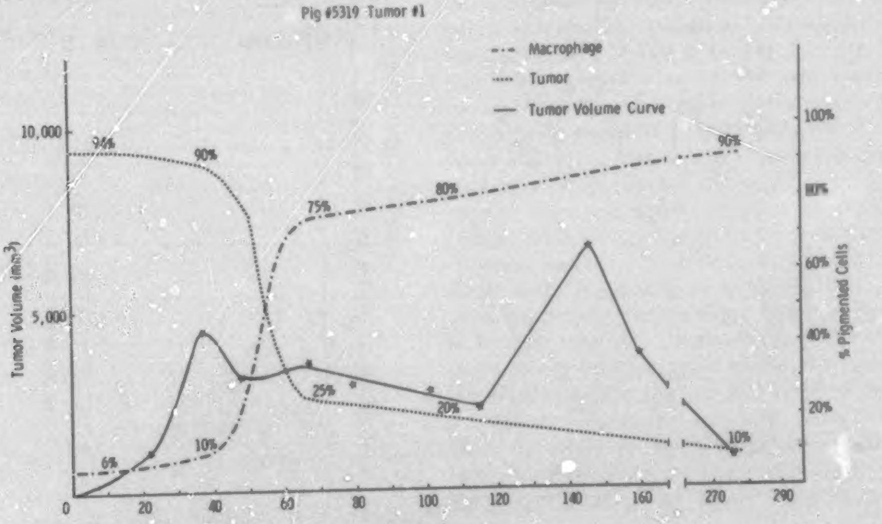
allogeneic swine melanoma cells. The results shown in text-figure 1B indicate that the samples collected from swine #5319 were substantially more reactive (52 and 14% survival or 48 and 86% reactivity) than were the samples collected from swine #5338 (99 and 84% survival or 1 and 16% reactivity).

Sequential histologic sampling was performed on pig #5319, tumor #1. Text-figure 2 compares measured tumor volume to the content of PLM and tumor cells. We have arbitrarily assigned the sum of tumor cells and macrophages to be 100%, although we are well aware that other cellular and noncellular elements contribute to tumor volume. At the time of maximum tumor volume, approximately 90% of the pigmented cells were macrophages and only 10% were malignant cells, which corresponds to an in vitro tumor cell survival of 52%.

Figures 1 and 2 illustrate the two extremes in the growth and regression of the cutaneous melanoma. Figure 1 is a histologic example of early tumor growth (day 10) when more than 90% of the pigmented cells were tumor cells. At a much later time (276 days), the regressed tumor was characterized by complete epidermal depigmentation (fig. 2) with isolated large nests of PLM in the dermis.

To determine if longitudinal leukocyte reactivity could be correlated with in vivo measured tumor volumes of swine melanoma, we tested the sequential reactivities of 7 swine in the visual microcytotoxicity assay. Leukocytes were collected and cryopreserved at 2- to 4-week intervals during the first 3–6 months after birth. All leukocyte samples from individual swine were thawed and tested on the same day. Text-figure 3 indicates that cryopreserved leukocytes that were from a single swine and that were tested on four different dates exhibited essentially the same pattern of sequential reactivity on all four dates.

The sequential reactivities of the 7 swine were compared to their in vivo tumor growth. All 7 swine exhibited easily

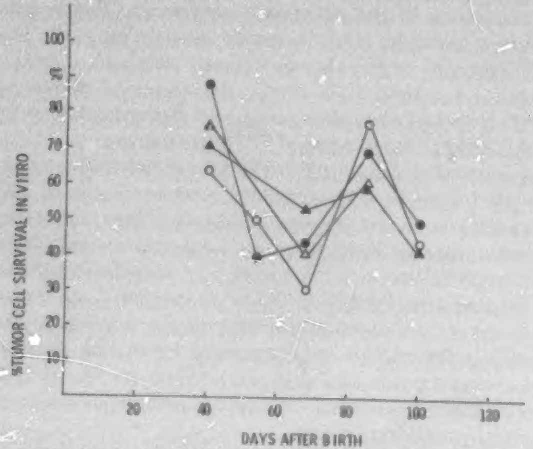


TEXT-FIGURE 2.—Sequential tumor volume measurements (—★—) compared to relative changes in numbers of malignant cells (····) and PLM (—·—).

detectable decreases in tumor volume during the period of observation. Four of the swine had maximum tumor volumes less than 30,000 mm^3 (text-fig. 4), and 3 swine had maximum tumor volumes greater than 30,000 mm^3 (text-fig. 5). The pattern of leukocyte reactivity in the 4 swine with relatively small tumor burdens (text-fig. 4) followed quite closely the pattern of tumor growth. In general, for tumor volumes less than 30,000 mm^3, tumor cell survival in vitro increased when in vivo tumor volume increased and decreased when in vivo tumor volume decreased. Swine #6003, which had the smallest tumor burden (maximum, 6,000 mm^3), exhibited the least variation in leukocyte reactivity throughout the period of tumor growth and regression.

In the 3 swine with maximum tumor volumes greater than 30,000 mm^3 (text-fig. 5), a consistent trend in reactivity was also observed, but this trend was different from that of swine with smaller tumor burdens. In the swine with large tumors, a substantial increase in in vivo tumor volume was accompanied by an *increase* in leukocyte reactivity (i.e., a decrease in in vitro tumor cell survival). This dramatic increase in leukocyte reactivity was followed by a refractory period with a subsequent return to increased reactivity as the tumor volume continued to decrease.

One tumor from pig #5434 was sampled for histologic examination at 42 and 71 days. Text-figure 6 illustrates that, as the tumor volume decreased, the number of malignant cells decreased, while the relative percentage of macrophages increased. This decrease in tumor cells was paralleled by a decrease in in vitro survival.



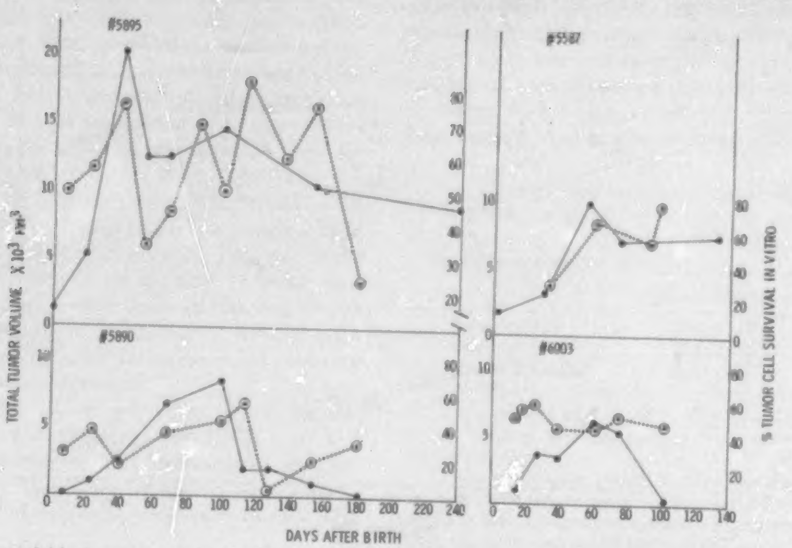
TEXT-FIGURE 3.—Sequential leukocyte reactivity of cryopreserved leukocytes from swine #5895 tested on 4 different days: ●=tested Jan. 30, 1981; ○=tested Feb. 16, 1981; ▲=tested March 10, 1981; △=tested May 19, 1981.

DISCUSSION

The results of the present study demonstrate that cryopreserved leukocytes from melanoma swine can be used to evaluate sequential leukocyte reactivity throughout the in vivo growth and spontaneous regression of Sinclair swine melanoma. Leukocyte reactivity was assayed by a visual microcytotoxicity technique, which utilized small numbers of tumor cells and leukocytes. Plating leukocytes in mixed patterns over the entire plate minimized position effects and prevented subjectivity during visual counting.

Initial comparisons of leukocyte reactivity in swine #5319, which had many small regressing tumors, with reactivity in swine #5338, which had a single large progressively growing tumor, suggested an association between in vitro leukocyte reactivity and in vivo tumor volume (text-fig. 1). Leukocyte reactivity was significantly greater in the swine with the slower rate of tumor growth and lower tumor volume (#5319).

Longitudinal studies of leukocyte reactivity in an additional 7 melanoma swine (all of which ultimately had complete tumor regression) indicated two patterns of leukocyte responses, both of which could be associated with

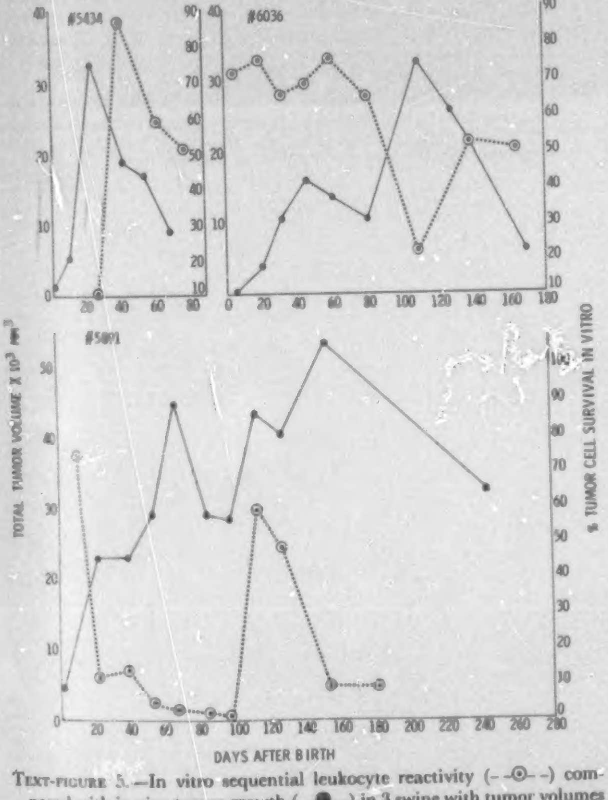


TEXT-FIGURE 4.—In vitro sequential leukocyte reactivity (- -⊙- -) compared with in vivo tumor growth (—●—) in 4 swine with tumor volumes <30,000 mm^3. *Left vertical axes* represent in vivo tumor volume; *right vertical axes* represent in vitro percent tumor cell survival.

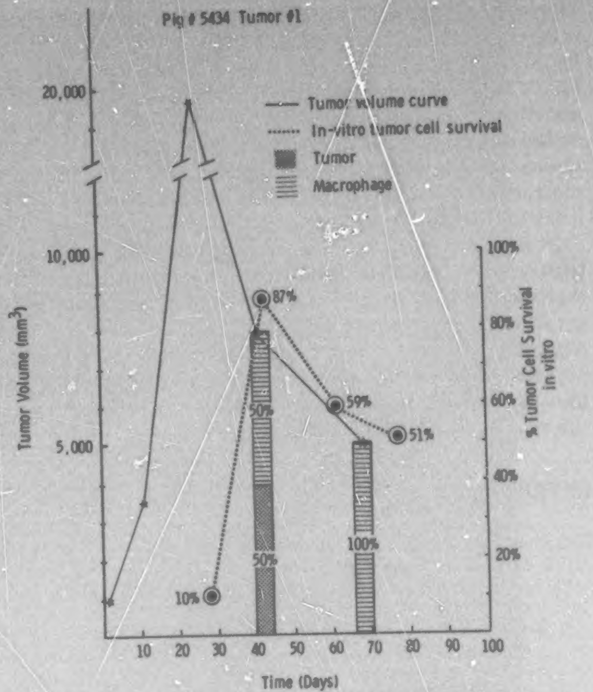
changes in cutaneous tumor volume. In swine with cumulative tumor volumes less than 30,000 mm^3, substantial increases and decreases in tumor volume were paralleled by increases and decreases in in vitro tumor cell survival (text-fig. 4). In 1 swine (#6003), which had an extremely small tumor burden, little variation in leukocyte reactivity was observed throughout the 3 months of observation. This lack of variation may have resulted from a low level of sensitizing tumor antigen in the circulation, possibly due to the fact that tumor cells were confined to the epidermis, which lacks a vascular supply.

In 3 swine with tumor volumes greater than 30,000 mm^3, a peak in in vivo tumor volume was accompanied by low in vitro tumor cell survival (i.e., high leukocyte reactivity) (text-fig. 5). Histopathologic analysis of tumor biopsy specimens indicated that the period of maximum increase in tumor volume could be attributed, in part, to infiltration by host inflammatory cells, especially by PLM (*13*). Therefore, the increase in tumor volume, rather than representing neoplastic cell growth, actually may have been a sign of in vivo tumor regression.

The cutoff point of 30,000 mm^3 was chosen empirically because the leukocyte reactivity divided naturally into these 2 groups. Although most lesions in this study were not examined by biopsy procedures, biopsy data from other melanoma swine suggest that the individual tumors that comprised the cumulative tumor volumes probably exhibited a histologic spectrum ranging from noninvasive to frankly invasive melanomas.



TEXT-FIGURE 5.—In vitro sequential leukocyte reactivity (- -⊙- -) compared with in vivo tumor growth (—●—) in 3 swine with tumor volumes >30,000 mm^3. *Left vertical axes* represent in vivo tumor volume; *right vertical axes* represent in vitro percent tumor cell survival.



TEXT-FIGURE 6.—Sequential changes in tumor volume (—★—) of a *single* cutaneous malignant melanoma in relation to in vitro leukocyte reactivity (- -⊙- -). Total height of the two bars at 42 and 69 days represents 100% of the pigmented cells comprising the tumor volume on those days. The relative percentage of malignant cells is indicated by ▩ and of PLM by ▤.

In this study, the swine with larger cumulative tumor volumes tended to have larger individual melanomas, while swine with smaller cumulative volumes usually had multiple smaller tumors. Previous biopsy data have indicated that palpable tumors having low volumes may consist of purely intraepidermal proliferation of neoplastic melanocytes with the palpable components contributed by PLM in the dermis. More definitive conclusions concerning the relationship of leukocyte reactivity to melanoma growth and regression require that sequential biopsies be performed on every tumor. Such studies are currently under way.

Initial increases in leukocyte reactivity, particularly in swine with larger tumors, were followed consistently by a transient decrease in reactivity. The reasons for this "eclipse" in in vitro reactivity are not known. However, the decrease in reactivity could have resulted from either a decrease in stimulating tumor antigen as a result of regression or from the release of antigen–antibody complexes which might block the leukocyte response. Several investigators (*14–16*) have reported transient losses in leukocyte reactivity after surgical removal of tumor or radiotherapy in cancer patients.

The effector cell population has not been purified and is composed of the entire PBL layer recovered from a Ficoll–

Hypaque gradient. Thus we cannot at this time identify the cell(s) responsible for the reactivity. In light of recent reports by other investigators on NK activity in melanoma patients (*17*, *18*), we will be interested in determining if the NK activity in Sinclair melanoma swine is increased during melanoma regression. In addition, since PLM are the most numerous cells found in biopsy specimens of regressing swine melanomas, we would like to determine if monocytes participate in the in vitro leukocyte response.

In conclusion, these results indicate a strong relationship between the spontaneous regression of swine melanoma and increased in vitro leukocyte reactivity. These studies do not prove that host immunologic responses cause the in vivo regression. However, they do indicate that the regression process is associated with a host immunologic response and that in vitro assays of leukocyte reactivity are useful indicators of in vivo antitumor immunity.

Ganglioside Changes Induced by Tumor Promoters in Promotable JB6 Mouse Epidermal Cells: Antagonism by an Antipromoter[1]

Leela Srinivas[2] *and* Nancy H. Colburn[2, 3, 4]

ABSTRACT—Since cell surface gangliosides have been implicated in the regulation of cell growth and differentiation and since tumor-promoting phorbol esters produce a number of membrane changes, the possibility was investigated that ganglioside changes may play a role in promotion of transformation in JB6 mouse epidermal cells. The studies showed that tumor-promoting but not non-promoting phorbol esters produced decreased precursor incorporation into trisialoganglioside G_T and increased incorporation into disialoganglioside GD_1b and an unknown ganglioside, G_X. These ganglioside responses to promoters were antagonized by the antipromoter retinoic acid, thus suggesting that alterations in ganglioside levels may be involved in promotion of transformation.—JNCI 1982; 68:469–473.

TPA is a highly active tumor promoter, having a wide range of effects on cultured cells (*1–9*). TPA and other tumor promoters promote anchorage independence and tumorigenicity in JB6 mouse epidermal cells (*2–4*). These cells are useful as a model for studying late-stage tumor promotion because they respond to promoters with an irreversible shift to tumor cell phenotype as measured by anchorage independence. Promoter-induced anchorage-independent JB6-derived cell lines are also tumorigenic as determined by injection into nude mice (*3*). TPA also elicits a number of plasma membrane and other glycoprotein changes, such as fibronectin and collagen loss, stimulated hexose uptake, inhibited binding of epidermal growth factor, and stimulated phospholipid synthesis (*1, 10–13*). One hypothesis of tumor promotion proposes that the promoting activity is mediated by specific plasma membrane changes. A candidate for membrane-mediated changes could be glycolipids, which are postulated to function in the regulation of cell growth and morphology (*14–16*). Among the glycolipids, gangliosides are of interest to study because they function specifically in the binding of fibronectin (*17*), cholera toxin (*18*), tetanus toxin (*19*), thyroid-stimulating hormone (*20*), and serotonin (*21*). Glycolipids have been implicated in the induction and maintenance of malignant transformation (*14*). Gangliosides in particular are sensitive to viral and chemical transformation (*22–26*). Specific ganglioside changes are brought about by TPA-induced differentiation in human melanoma cells (*7*).

Retinoids have been shown to be antipromoters both in vivo and in cell culture (*9, 27, 28*). Promotion of anchorage independence and tumorigenicity by TPA in JB6 cells is blocked by retinoids (*4, 28*). It was therefore of interest to investigate whether ganglioside synthesis might be a target for the tumor-promoting action of phorbol esters and for the anti-tumor-promoting action of retinoids. We report here that promoting but not nonpromoting phorbol esters induce specific ganglioside changes in promotable JB6 cells and that these changes are prevented by the antipromoter RA.

MATERIALS AND METHODS

Chemicals.—TPA and its ester analogs were purchased from Dr. Peter Borchert, Chemical Carcinogenesis (Eden Prairie, Minn.), and were stored at −20°C in a desiccated container at 1 mg/ml concentration in spectral grade DMSO. At the time of use they were diluted appropriately in the medium in which the concentration of DMSO was always 0.1% or less. RA was a gift from Hoffmann-La Roche Inc. (Nutley, N.J.) and was used at 10^{-6} *M* final concentration under yellow light. Bovine brain gangliosides and standard individual gangliosides G_{M1}, G_{D1a}, and G_T were purchased from Supelco, Inc. (Bellefonte, Pa.). D-[1-^{14}C]glucosamine hydrochloride (55 mCi/mmol) was procured from Amersham/Searle Corp. (Arlington Heights, Ill.). Solvents used were of analytic grade from Fisher Scientific Co. (Fair Lawn, N.J.). Silica Gel-G plates were purchased from Analtech, Inc. (Newark, Del.). *Clostridium perfringens* neuraminidase was purchased from Boehringer Mannheim Biochemicals (Indianapolis, Ind.), and *N*-acetylneuraminic acid was purchased from Sigma Chemical Co. (St. Louis, Mo.).

Cell culture.—The JB6 cell line was derived from mouse primary epidermal cell cultures as described by Colburn et al. (*2, 29*). These cells were passed by trypsinization (0.06% trypsin), and cultures were always maintained in logarithmic growth. Cells were grown in 15-cm petri dishes in minimum essential medium with Earle's salts (GIBCO, Grand Island, N.Y.) and were supplemented with 8% fetal calf serum (Flow Laboratories, Inc., Rockville, Md.) and antibiotics.

TPA exposure and labeling.—TPA was added to the cells at 10 ng/ml (1.6×10^{-8} *M*) concentration (unless otherwise stated in 5% fetal bovine serum medium), and time of exposure was 24 hours. The cells were terminally labeled with D-[1-^{14}C]glucosamine hydrochloride for 4 hours at a final concentration of 4 μCi/ml. DMSO controls were always included, and all experiments were conducted in duplicate or triplicate.

Ganglioside isolation.—The medium was removed, and cells were washed thoroughly with phosphate-buffered saline and scraped in 4 ml methanol to which 8 ml chloroform was

ABBREVIATIONS USED: DMSO=dimethyl sulfoxide; RA=retinoic acid; R_f=retardation factor(s); TLC=thin-layer chromatography; TPA=12-*O*-tetradecanoylphorbol 13-acetate.

then added. The gangliosides were isolated according to the procedure of Suzuki (*30*) as modified by Langenbach (*31*). This method involved sonication of cells in chloroform:methanol (2:1; vol/vol) in the presence of 100 µg bovine brain gangliosides followed by removal of cell debris. Water was added to one-fifth of the total volume and mixed thoroughly. The upper phase containing gangliosides was removed and saved. The lower phase was carefully washed with the theoretical upper phase (48:47:1) (CH_3OH:H_2O:$CHCl_3$; vol/vol/vol), and the washes were combined with the upper phase. The upper phase was dialyzed in boiled and washed dialysis bags against distilled water for 24 hours at 4°C. The contents of the dialysis bag were lyophilized and dissolved in chloroform:methanol (2:1; vol/vol). Gangliosides were separated by thin-layer chromatography on Silica Gel-G-coated plates with a solvent system of chloroform:methanol:ammonium hydroxide:water (60:35:0.5:7.5; vol/vol/vol/vol). This solvent system separates gangliosides clearly from the origin due to the low concentration of ammonium hydroxide used. The gangliosides were identified by cochromatography with authentic standards. The gangliosides' R_f were G_X (an unidentified ganglioside): 0.08; G_T: 0.18; G_{D1b}: 0.3; G_{D1a}: 0.38; G_{M1}: 0.48; G_{M2}: 0.8; and G_{M3}: 0.95. The mode of ganglioside detection was by exposure to iodine vapor with the lid of the chamber open to a slit. The stained bands were marked, and iodine was allowed to sublime. We determined the incorporation of [^{14}C]glucosamine by scraping the band, extracting the ganglioside into 1.0 ml of chloroform:methanol:water (10:10:1; vol/vol/vol), and counting in a Beckman liquid scintillation counter with the use of Hydroflour as scintillant. The efficiency of ganglioside extraction from the TLC plate was 80–90% for all gangliosides. Scintillation counting efficiency in 1.0 ml solvent was 50%. The nomenclature of the gangliosides is that of Svennerholm (*32*).

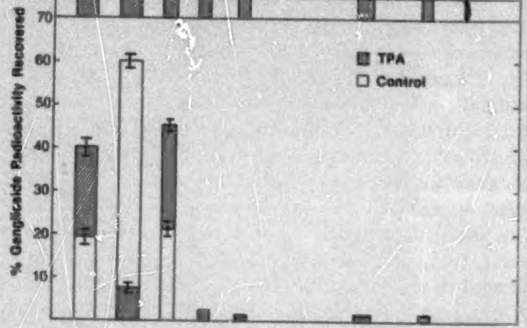
Neuraminidase assay.—JB6 mouse epidermal gangliosides G_X, G_T, and G_{D1b} were scraped off the plate and used as substrates. The incubation medium contained purified ganglioside (±5 µg sialic acid), 100 µl of 200 m*M* acetate buffer (pH 5.2) containing 2 m*M* calcium chloride plus or minus 0.1 U enzyme (50 µl), and water to a final volume of 200 µl. The reaction mixture was incubated for 4 hours at 37°C, and the reaction was stopped by addition of 10 volumes of $CHCl_3$:CH_3OH (2:1 vol/vol). The mixture was evaporated under a stream of nitrogen and dissolved in chloroform:methanol (1:1; vol/vol). An aliquot was applied to a Silica Gel-G plate that was prerun with a solvent system of petroleum ether:diethyl ether:acetic acid (80:20:1; vol/vol/vol) and dried overnight. This system obviates the need to desalt the reaction mixture and does not interfere with separation of gangliosides with the use of the previously mentioned solvent system (*33*) but yields different R_f.

RESULTS

TPA exposure for 24 hours produced about a 50% decrease in de novo synthesis of total gangliosides as measured by a terminal 4-hour incorporation of D-[1-^{14}C]glucosamine. Separation of gangliosides by TLC gave the following R_f, as illustrated in text-figure 1: G_X (an unidentified ganglioside): 0.08; G_T: 0.18; G_{D1b}: 0.30; G_{D1a}: 0.38; G_{M1}: 0.48; G_{M2}: 0.8; and G_{M3}: 0.95. Determination of the distribution of precursor incorporation into individual gangliosides revealed that TPA produces three specific changes in ganglioside synthesis (text-fig. 1). The precursor incorporation into a trisialoganglioside G_T decreased eightfold to tenfold, while incorporation into an unidentified ganglioside G_X and a disialoganglioside G_{D1b} increased twofold. That the unknown band G_X is a ganglioside is indicated by three observations: *a*) It shows incorporation of palmitic acid and is therefore a lipid and not a glycopeptide. *b*) It gives a positive reaction with resorcinol, thereby indicating the presence of sialic acid moieties. *c*) When treated with *C. perfringens* neuraminidase (fig. 1), G_X from JB6 cells is completely converted to monosialoganglioside G_{M1}. This result is expected for complex gangliosides and in fact occurs for the other complex JB6 gangliosides G_T and G_{D1b} as shown in figure 1, lanes 3 and 4.

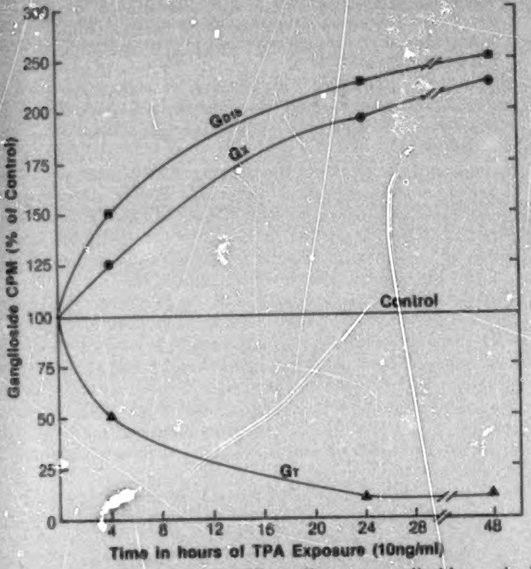
The TPA-sensitive gangliosides have been identified on the basis of the solvent system shown in text-figure 1 as well as on the basis of two others. These included *N*-propanol:water (7:3; vol/vol) and chloroform:methanol:0.25% $CaCl_2$ (60:35:8; vol/vol/vol). However, the identities of these gangliosides are exclusively based on TLC. More exact methods of identification, such as gas-liquid chromatography and mass spectrometry, are being developed in our laboratory to determine the structure (Muschik G, Srinivas L, Colburn NH: Unpublished data).

The TPA-induced changes in ganglioside synthesis were observed as early as 0–4 hours after TPA exposure and persisted for at least 48 hours (text-fig. 2). Maximal effects were observed by 24 hours of exposure to TPA. The time course suggests coordinate regulation by TPA of shifts in the synthesis of all three gangliosides (G_T, G_X, and G_{D1b}).

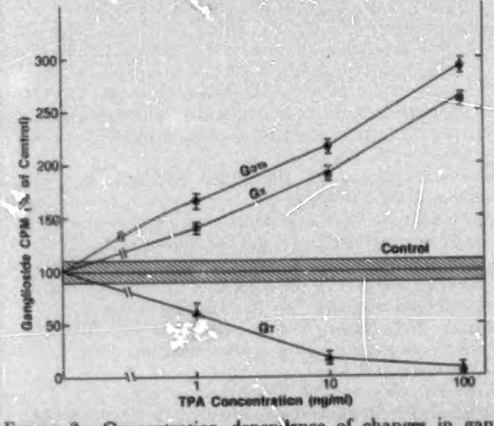


TEXT-FIGURE 1.—TPA treatment of JB6 cells produces a specific decrease in D-[1-^{14}C]glucosamine incorporation into trisialoganglioside G_T and an increase in incorporation into G_{D1b} and G_X. Gangliosides were separated on precoated Silica Gel-G plates (250 µm) with $CHCl_3$:CH_3OH:NH_3OH:H_2O (60:35:0.5:7.5; vol/vol/vol/vol). Plates were exposed to iodine vapors, and ganglioside bands were marked. After the iodine sublimed, the gangliosides were scraped, dissolved in $CHCl_3$:CH_3OH:H_2O 10:10:1; vol/vol/vol), and counted in a scintillation counter with Hydroflour at an efficiency of 50% for 1-ml samples. The radioactivity incorporated into each ganglioside was expressed as percent of total ganglioside-associated radioactivity with I indicating the range of duplicates. The radioactivity recovered from the plate was 80–90% of the total activity applied. Ganglioside-associated radioactivity recovered from control plates was ≈2,000 cpm, and from TPA-treated plates it was ≈1,100 cpm from a typical experiment. OR=origin; SF=solvent front.

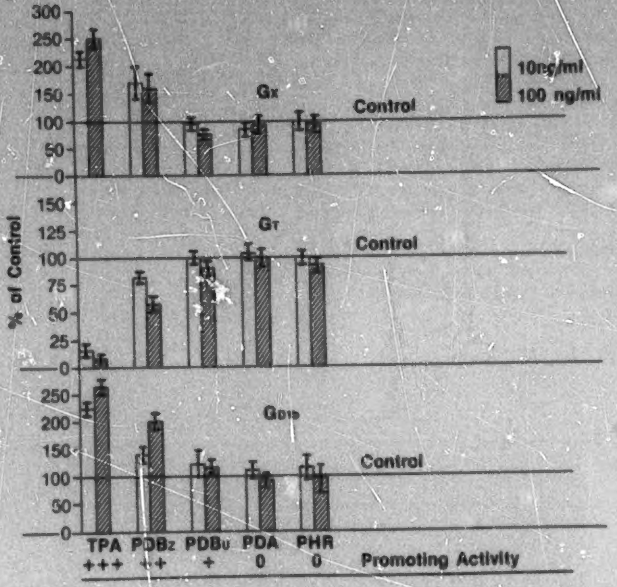
The variation of ganglioside response with TPA concentration (text-fig. 3) indicates a correlation with the promotion of tumor cell phenotype by JB6 cells. As reported previously (*2*), 1-100 ng TPA/ml is active in promotion of anchorage independence with 10 ng/ml showing near-saturating activity. The 10-ng (1.6×10^{-8} *M*) TPA/ml concentration also appeared to be near saturating for the G_T decrease. To ascertain whether the changes are promoter-specific, we tested several analogs of TPA. The order of promoting activity in vivo and in JB6 cells in culture (*2*) for phorbol esters tested at 100 ng/ml was TPA>phorbol 12,13-dibenzoate>phorbol 12,13-dibutyrate>phorbol 12,13-diacetate=phorbol. As shown in text-figure 4, the non-tumor promoters phorbol 12,13-diacetate and phorbol showed no activity; the weak promoter phorbol 12,13-dibutyrate showed little or no activity; and phorbol 12,13-dibenzoate, which is less active as a promoter than TPA, showed intermediate activity in producing ganglioside shifts.



TEXT-FIGURE 2.—Time course of TPA effect on ganglioside synthesis in JB6 cells. D-[1-^{14}C]glucosamine incorporation was done for the terminal 4 hr of TPA exposure. Control values (100%) represent the incorporation of [1-^{14}C]glucosamine obtained without TPA at each time point as a percent of total ganglioside-associated radioactivity. The graph shows the [1-^{14}C]glucosamine incorporation into each ganglioside compared to that of control at each time point. *Each point* is the mean value for duplicate dishes.



TEXT-FIGURE 3.—Concentration dependence of changes in ganglioside synthesis in response to TPA. TPA-induced changes in ganglioside synthesis (cpm [1-^{14}C]glucosamine incorporated as % of control) were determined as described in the legend to text-fig. 2. ▨=mean plus or minus the standard error of control values. ⟍=the range for duplicate TPA-treated samples.



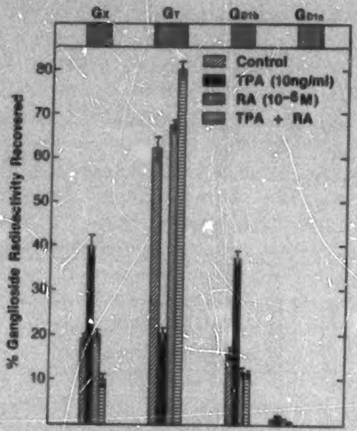
TEXT-FIGURE 4.—Ganglioside changes correlate with promoting activity of phorbol esters. [1-^{14}C]glucosamine incorporation into gangliosides was determined 20-24 hr after exposure to phorbol (PHR) or phorbol ester, and the results are expressed as described for text-fig. 2. I, the range of duplicate values. PDB_Z=phorbol 12,13-dibenzoate; PDB_U=phorbol 12,13-dibutyrate; PDA=phorbol 12,13-diacetate.

RA, an antipromoter both in vivo and in vitro (*9*), was investigated as a possible antagonist of TPA-induced ganglioside changes. Text-figure 5 shows the effects on ganglioside synthesis of an antipromoting concentration of RA alone or in combination with TPA. The 4-hour terminal incorporation of [1-^{14}C]glucosamine into gangliosides was unaffected by a 24-hour exposure to RA alone. In combination with TPA, RA completely prevented the TPA-induced changes in G_X, G_T, and G_{D1b}.

DISCUSSION

These studies have shown that tumor-promoting but not nonpromoting phorbol esters produce substantially decreased synthesis of G_T and increased synthesis of G_{D1b} and an unidentified ganglioside G_X in promotable JB6 cells. This observation, together with the demonstration that an antipromoting (*4, 27*) concentration of RA antagonizes the changes, suggests that the ganglioside response to TPA could be involved in promotion of transformation in JB6 cells.

The gangliosides affected by TPA in mouse JB6 cells differ from those involved in the TPA response in human melanoma cells (*7*). Undoubtedly, tissue and species specific-



TEXT-FIGURE 5.—Anti-tumor-promoting concentration of RA antagonizes TPA effects on G_X, G_T, and G_{D1b} synthesis. JB6 cells were treated with 10 ng (1.6×10^{-8} *M*) TPA/ml for 24 hr. RA (10^{-6} *M*) exposure was done alone or simultaneously with TPA. The cells were labeled with [1-^{14}C]glucosamine for the last 4 hr. Gangliosides were isolated, separated, detected, and counted as described in text-fig. 1.

ity can be expected to give rise to characteristic ganglioside profiles and responses to external stimuli as is found for a variety of other cell surface molecules.

The similar time courses of G_T, G_{D1b}, and G_X changes suggest that TPA triggers some coordinate control mechanism that affects all three gangliosides. Decreased activity of anabolic enzymes, such as a glycosyltransferase, or increased activity of a catabolic enzyme, such as a neuraminidase, might be involved in producing such coordinate regulation with G_T as a primary target. We have recently found that JB6 cells produce a neuraminidase that utilizes G_T as a substrate (Srinivas L, Colburn NH: Unpublished data). Such an activity could be a candidate for a mediator of the G_T response to TPA.

The observation that the promoter-induced changes in ganglioside synthesis are completely blocked by the antipromoter suggests that: *a*) These gangliosides are involved in promotion of transformation, and *b*) they may be the target of the antipromoting action of RA. We have recently reported that RA also antagonizes the TPA-induced collagen decrease (*13*) in JB6 cells. Since the time courses of the collagen and ganglioside responses to TPA are similar, coordinate regulation of the two events by RA might be possible. However, the data suggest that the pathways may be different for the antagonism of TPA-induced collagen and ganglioside changes since RA alone increases collagen levels (*13*) but is without effect on ganglioside levels (text-fig. 5).

Further evidence for a role of the G_T switch in promotion of transformation by TPA in JB6 cells comes from our recent observation that promotion-sensitive but not promotion-resistant variants consistently undergo this G_T decrease (*34*).

Microcirculatory Blood Flow, Capillary Morphology, and Local Oxygen Pressure of the Hamster Amelanotic Melanoma A-Mel-3 [1,2,3]

Bernhard Endrich, *M.D.*,[4,5] **Frithjof Hammersen**, *M.D.*,[6] **Alwin Götz**,[4,7] *and* **Konrad Messmer**, *M.D.*[4,8]

ABSTRACT—Transparent chambers and permanent indwelling catheters were implanted in the dorsal skin flaps of 24 inbred golden Syrian hamsters. After 48 hours, 4×10⁴ amelanotic melanoma cells (A-Mel-3) were transplanted sc (12 hamsters) in areas exposed for intravital microscopy. A platinum multiwire electrode and techniques for a quantitative analysis of television images were used for measurements of local oxygen pressure (P_{O_2}), capillary blood cell velocity, capillary density, and capillary diameter and length, whereas capillary morphology was evaluated by electron microscopy. Compared to the mean local P_{O_2} of the skin flaps of controls (12 hamsters), the mean local P_{O_2} on the tumor surface of melanoma-bearing hamsters decreased with tumor size. Although capillary density of the melanoma was elevated 4 days after tumor transplantation, it decreased significantly until day 12. Of hemodynamic significance were huge platelet conglomerates in short, dilated capillaries. Electron microscopy revealed endothelial hyperplasia, open endothelial junctions, and disintegration of the capillary endothelium. These findings strongly suggest that elevated microvascular resistance, intratumor tissue pressure, and widening of intercapillary distances in the melanoma might significantly diminish the impact of chemotherapeutic treatment.—JNCI 1982; 68:475–485.

One important feature of malignant melanomas is the unpredictability of growth and metastatic spread. A primary tumor as small as 5 mm³ can be accompanied by distant dissemination and metastases. In general, such small lesions reveal an established, characteristic microcirculatory pattern (*1-4*) on which cancer cells depend for maintenance and proliferation. The distribution of oxygen and nutrients at the capillary barrier is achieved after a distinct endothelial proliferation of postcapillaries and collecting venules into the tumor mass. By contrast, arterial blood is supplied to the tumor by morphologically normal arterioles (*5, 6*).

The total volume of blood supplying the malignant mass will, however, depend on both morphology and reactivity of arterioles and precapillaries located *in the tumor* as well as on the reactivity of the microcirculation in tissue *surrounding the tumor*. Only in vivo studies on single microvessels allow characterization of the structural and functional elements within the microvascular system. When transparent chamber techniques are used, the growth progression of malignant tumors and the alterations of their neovascular systems can be evaluated readily.

If these techniques are combined with a quantitative analysis of TV images, microhemodynamic parameters can be quantitated in individual vessels of both the melanoma and the surrounding subcutaneous structures. The present study reports on morphologic and microhemodynamic features of the hamster amelanotic melanoma A-Mel-3 with information gathered from in vivo and in situ observations.

MATERIALS AND METHODS

Quantitative analysis of the microcirculation.—Techniques of intravital microscopy and hemodynamic analysis in the terminal vascular bed have been described by Intaglietta and Zweifach (*7*) and by Zweifach and Lipowsky (*8*) (text-fig. 1) and were followed up with minor modifications of the optical system as reported previously (*9*). For microscopic observations and measurements, the original transparent double-frame-type chamber of Algire (*10*) was modified and aluminum chambers were implanted in the dorsal skin flaps of 24 hamsters, with the tissue thickness fixed at 450±5 µm. Because hamster skin is extremely translucent, such a large tissue thickness could be used, allowing for prolonged observation of a rapidly growing tumor. Two permanent indwelling catheters were inserted through the right jugular vein and the carotid artery and were directed toward the right and left ventricles, respectively (*9*).

After a 48-hour recovery from anesthesia and microsurgery, the hamsters' systemic pressures were monitored at 2-day intervals by Statham pressure transducers via both catheters. Concurrently, intravascular velocity of red blood cells was measured on-line from the photometric signal provided by two optical windows (Video Photometric Analyzer, model 204; IPM Inc., San Diego, Calif.) that were placed along the centerline of a given blood vessel within the televised site (*11*).

ABBREVIATIONS USED: FITC–Dextran 150=fluorescein isothiocyanate covalently bound to dextran, mol wt 150,000 (Pharmacia AB, Uppsala, Sweden); P_{O_2}=pressure of oxygen; TV=television.

TEXT-FIGURE 1.—Scheme of the optical and electronic system for in vivo studies of the microcirculation.

In vitro calibration of the velocity system was performed before the experiment by measurement of the velocity of a disk rotating in a plane tangential to the optical axis. The windows were aligned manually along lines previously scratched into the translucent disk at a known radius and were filled with (8–10 µm) silicon carbon particles. These particles modulated the light reflected from the translucent disk and provided a signal size of 0.2–0.3 V. Even though a rotating disk containing a freshly prepared blood smear yielded the same signal size, in vitro measurements provided by constant size particulate matter were found to be more reproducible over an extended time (due to the shrinkage and discoloration of blood cells).

By this modified technique, the velocity system demonstrated a linearity of within 5% for all velocities from 0 to 10 mm/second. Due to framing rate limitations of European TV standards, however, large window spacings between 50 and 200 µm were necessary to measure velocities above 2.5 mm/second in vitro. Velocities above 10 mm/second could not be measured because the distance between the two sensors exceeded the vertical axis of the TV monitor at the given magnification (900×).

In vivo, however, the maximum blood cell velocity that can be reliably measured with the photometric analyzer and European TV standards is limited to approximately 2.5 mm/second. As a result of larger window spacings required to measure higher velocities, the computation of other events, i.e., autocorrelation, diminished the sharpness of the peak cross-correlation due to the light scintillation of the bloodstream, hence decreasing its detectability (*11, 12*). This problem, however, could be neglected in our study because the velocity data obtained only occasionally exceeded 2.5 mm/second. Each value above 2.5 mm/second was double checked with both the photometric analyzer and the photodiode as described below.

Intravital microscopy and video recordings were obtained from selected areas in subcutaneous tissues of chamber-bearing animals that were not tumor bearing (n=12) and that were tumor bearing (n=12). The region selected covered at least 1,800×1,000 µm. To minimize bias, we selected the region on day 0 (48 hr after implantation of the chamber and before inoculation of the melanoma) entirely on the basis of tissue transparency and visibility of large blood vessels (20–40 µm). When transillumination is used, capillaries are barely visible in this chamber model; consequently, any measurement at the capillary level refers to a single blind selection of this type of microvessel. After being committed to one region, we could better visualize the microvascular beds with the use of fluorescent microscopy after the hamsters received iv injections of 0.2 ml of 5% FITC-Dextran 150. This technique improved the poor contrast in vivo between the vessel wall of larger vessels and capillaries, the adjoining tissue, and the vascular contents to such an extent that blood cells were delineated as dark structures versus a bright background of plasma. Since microvascular entities were analyzed in a "dynamic" system, a given region could be as large as 5,000×3,500 µm, a size that then required several separate photomontages for microvascular analysis (*12*). In each animal, the identical area was observed throughout the experiment.

Videotape recordings needed for measurements of blood cell velocities and vascular diameters were performed in restrained, unanesthetized animals. At the conclusion of the experiments, the videotapes were played back, and the raster-line signals produced by the movement of blood cells were passed through the Video Photometric Analyzer. The comparison of velocity data from the videotape with data obtained during the recording procedure did not show any differences and the velocity data were not related to the use of either the Video Photometric Analyzer or a photodiode (fiber optic pickup system; IPM Inc.) which should be used for European TV standards if the velocity exceeds 2.5 mm/second (*11*). However, data from videotape recordings were included in this study primarily for the following reasons: 1) to shorten the time needed to restrain the unanesthetized animal for observation and videotape recordings, 2) to allow sufficient time for analysis because a dense capillary network (mean intercapillary spacing, ≈10 µm) was consistently seen providing a redundancy of information, and 3) to allow a double check of measurements by the principal investigator.

By measuring blood cell velocity and diameter in each vessel supplying the tumor with blood, we could calculate volume flow through any "inflow" vessel and thus, by addition of volumetric blood flows of all feeding vessels, could obtain total volume flow to the tumor. The conversion of these values into the usual dimension of blood flow (ml/min/100 g) was done by the calculation of the tumor weight. To calculate the tumor weight, we measured the tumor radius from the opaque area associated with the presence of the tumor, and we determined the equivalent radius of a circle covering the same surface. Since the tissue thickness was known (450 µm), the tumor volume and weight (specific density assumed to be 1) were readily calculated by the multiplication of the tumor surface by the tissue thickness. The blood inflow (ml/min/100 g) was determined by division of the total volumetric flow through the calculated tumor weight and by multiplication of this value by 100 (g).

On various days, we used a platinum multiwire electrode to measure local Po_2 on the surface of subcutaneous tissue (*13, 14*). The design of this Po_2 electrode consists of eight 15-μm-diameter platinum wires sealed in glass and covered with a Teflon membrane. The electrode registers O_2 tension on the tissue's surface simultaneously at eight different positions in a hemispherical catchment area of 30–50 μm. A micromanipulator was used to place the electrode on the tissue preparation after the cover glass was lifted from the chamber. By controlled movement of the electrode on the tissue's surface, a statistical distribution of Po_2 values could be obtained. The data are shown as Po_2 histograms.

During the Po_2 measurements, the local temperature was measured in the subcutis (small animal temperature probe; Ellab Instruments, Copenhagen, Denmark) and on the tumor's surface. This parameter remained constant in all animals (mean value ± SEM: 30.1±0.1°C).

Morphologic studies of the vascularization patterns were performed by construction of photomontages from black-and-white prints taken from the TV monitor at 500× (final magnification of printed montage=150×). The size of the areas selected in the preparation was measured from montages by a planimeter with an accuracy of ±5%. Lengths of vessels within a given area were also measured from the montage by the use of a map measure (*15*). In addition, an electronic video-image shearing technique was used to determine the internal vessel diameter for all vessels in which velocity measurements were made. This was performed at an effective magnification of 600×, as observed on a TV monitor (*16*). For morphometric measurements of capillary density, i.e., the density of FITC–Dextran 150-stained visible capillaries, the total length of vessels per unit area was calculated by stereologic techniques (*15*).

A rectangular grid was superimposed on the vessel's overlay. The total number of intersections between vessels and grid within a designated area were counted. If one assumes a random orientation of individual vessels, capillary density (L_A) was calculated from the probability of these intersections according to the equation $L_A = \pi \cdot N \cdot X / 2L_G$ (cm^{-1}), where N equals the number of intersections between vessels and grid, X equals the total magnification, and L_G equals the total length of grid lines enclosed in the designated area.

For routine L_A counts at 150×, a grid spacing of 10 mm was chosen. Despite a spacing of 450 μm between the two chamber frames, the depth of focus, as obtained by epi-illumination and fluorescent microscopy, was approximately 70 μm. This value is within the limits for the analysis of a three dimensional structure (*15*); consequently, the capillary density was analyzed precisely as described by Schmid-Schoenbein et al. (*15*). Routine histologic sections from tumor and controls confirmed that the vasculature studied in vivo very much resembled the typical microvascular pattern of the melanoma and subcutaneous tissue, respectively. Furthermore, all feeding vessels were found within this depth of focus.

Preparation and inoculation of tumor cells.—Tumor cells were received from a solid, virus-induced amelanotic melanoma A-Mel-3 established by Fortner et al. (*17*) from hamster cells. After sc injection of 1×10^6 cells in the hamster's back, a solid tumor 2 cm in diameter grew within 14 days. The tumor became necrotic by that time and killed the animal within 3 weeks. Before becoming necrotic, the tumor was maintained by being passed once every other week in inbred Syrian hamsters and was harvested by being sterilely excised. Cell suspensions of sterile hamster melanoma cells were stored in RPMI-1640 medium containing 10% fetal calf serum plus 10% dimethyl sulfoxide and kept frozen in liquid nitrogen. After a rapid thaw to 37°C, the cells were washed three times in RPMI-1640 medium plus 1% penicillin–streptomycin and checked for viability by trypan blue exclusion. Usually, 70–80% of the tumor cells were alive.

For tumor cell transplantation in the chamber preparation, 1 μl (microliter syringe; Hamilton, Bonaduz, Switzerland) of a concentrated tumor cell suspension was inoculated 48 hours after the chamber was implanted. This measure served to distinguish trauma-induced neovascularization from the development of capillary buds due to tumor growth. We evaluated the precise number of living cells by counting several samples with identical volumes and then adjusting the number of cells to 35,000–40,000 living tumor cells. All animals were housed in single cages in an environment that was controlled at 28°C. After tumor cells were inoculated, animals bearing the melanoma as well as control animals were kept for 4 days at 35°C and 50% humidity (Intensive Care Incubator 7510; Dräger, Lübeck, Federal Republic of Germany). This measure increased the tumor take to more than 90%. As the tumor became vascularized after 4 days, the environmental temperature was decreased to 28°C. All videotape recordings and measurements were done in animals taken from the 28°C environment and placed under the microscope. As mentioned earlier, the local subcutaneous temperature was constant at 30.1°C in the unanesthetized animal.

RESULTS

Microvascular Pattern of Amelanotic Melanoma A-Mel-3

The tumor portion in the tissue chambers was usually ovoid (fig. 1) with 1–4 vessels of arteriolar dimension and a moderate number of precapillaries feeding the melanoma. A narrow zone of edematous connective tissue separated the periphery of the tumor from a leash of dilated capillaries and collecting venules that surrounded the tumor (fig. 2). All of these vessels appeared to have thin walls lined by a single endothelial layer. There were also a few residual vessels remaining from those long, parallel capillaries at the inoculation site, which were typical of skeletal muscle tissue.

Direct attachment of tumor cells to capillaries was seen (fig. 3) and was frequently associated with formation of thrombi. Electron microscopy further revealed occasional diapedesis of erythrocytes (fig. 4). After approximately 4 days, a typical vascular configuration of short, thin-walled, sometimes dilated capillaries was seen primarily at the edge of the tumor (fig. 5). The appearance of these new blood vessels was associated with rapid growth of the malignant tissue. By 12 days after transplantation, the radius of the tumor portion became 2,718±664 μm. Due to continuous growth, the tumor obscured the preparation after 18 days, and observations in the microvasculature of the tumor were no longer possible.

The length of capillaries revealed a statistically significant difference ($P<0.02$–<0.005, Student's paired *t*-test) between tumor-bearing and control animals. The average capillary length in amelanotic melanoma was 198.2±8.9 µm on day 4 and 230.5±10.3 µm 8 days later (text-fig. 2). Capillary length in subcutaneous tissue of control tumor-free animals was 414.4±30.9 µm on day 4 and 418.5±21.8 µm on day 12, i.e., 14 days after implantation of the aluminum chamber.
